VOLUME 1

Fundamentals and History of Development of Nuclear Energy

Introduction to Fundamentals and History of Development of Nuclear Energy <i>Eric B Norman</i>	1
What Is the Universe Made of? <i>Alejandro Garcia</i>	3
Discovery of Radioactivity <i>Daniel E DiGregorio</i>	9
Discovery of the Quantum Structure of Atoms and Their Nuclei <i>Kenneth S Krane</i>	19
Origins of Nuclear Energy <i>Jim Napolitano</i>	29
Radioactive Decay <i>E Previtali</i>	35
Nuclear Fission I <i>Jennifer L Klay</i>	45
Nuclear Fission II <i>Andrew E Stuchbery</i>	53
Fissile and Fertile Fuels <i>Jennifer Shusterman</i>	66
Manhattan Project <i>B Cameron Reed</i>	78

Nuclear Fusion <i>Edward C Morse</i>	92
Atomic and Hydrogen Bombs <i>Jim Napolitano</i>	101
Phenomenology of Neutron Interactions <i>Fred E Wietfeldt</i>	107
Phenomenology of Gamma Ray and Charged Particles Interactions <i>Reina Maruyama</i>	117
Radiation Sources <i>David K Wehe</i>	125
Experimental Tools I: Radiation Detectors <i>Ke Han</i>	133
Experimental Tools II: Particle Accelerators <i>Alejandro Garcia</i>	146
Commercial Nuclear Power Reactors and their Design	
Commercial Nuclear Power Reactors and Their Design—Introduction <i>Russell E Stachowski</i>	153
History of PWR and BWR Development <i>Jeffery A Brown and G Ivan Maldonado</i>	157
Physics of the Fission Chain Reaction in Thermal and Fast Reactors <i>Pavel V Tsvetkov and Russell E Stachowski</i>	172
Principles of Design and Operation of Nuclear Power Reactors <i>David A Hamon</i>	187
Pressurized Water Reactors <i>Jeffery A Brown</i>	196
Boiling Water Reactors <i>David A Hamon</i>	214
Heavy-Water Reactors <i>Eleodor Nichita</i>	236
Commercial Nuclear Power Plant Statistics <i>David A Hamon</i>	252
Pros and Cons of Commercial Reactor Designs Part 1: Current Status of Electricity Generation in the World and Selected Countries <i>I Pioro, RB Duffey, PL Kirillov, and R Pioro</i>	263
Pros and Cons of Commercial Reactor Designs: Part 2—Current Status and Future Trends in the World Nuclear-Power Industry and Technical Considerations of Nuclear-Power Reactors <i>I Pioro, RB Duffey, PL Kirillov, and R Pioro</i>	288
Economics of Nuclear Energy <i>Geoffrey S Rothwell</i>	304

Economic Challenges of Nuclear Energy <i>Geoffrey S Rothwell</i>	317
Fuel Rod, Fuel Assembly, and Reactivity Control Assembly Design <i>Michael Y Young</i>	327
Heat Transfer Systems <i>Karen Vierow Kirkland</i>	345
Instrumentation and Control Systems of Nuclear Power Plants <i>Belle R Upadhyaya and Richard T Wood</i>	373
Reactor Operations <i>Michael Y Young</i>	393
Operational Analysis Methods <i>William Walters</i>	405
Transient Analysis Methods <i>RP Martin</i>	422
Containment <i>Phil Sharpe</i>	439
Design of the Balance of Plant <i>M Arcaro</i>	446
Safety of Nuclear Reactors <i>Nicholas R Brown and Seok Bin Seo</i>	456
Management of the Nuclear Waste – Via Disposition or Transmutation <i>Pavel V Tsvetkov</i>	465
Advanced Nuclear Reactor Concepts Under R&D	
Worldwide Status of Advanced Reactors (GEN IV) Research and Technology Development <i>Alexander Stanculescu</i>	478
Sodium-Cooled Fast Reactors <i>F Heidet</i>	490
The High Temperature Gas-Cooled Reactor <i>Michael A Fütterer, Gerhard Strydom, Hiroyuki Sato, Fu Li, Eric Abonneau, Tim Abram, Mike W Davies, Minwhan Kim, Lyndon Edwards, Ondrej Muransky, Manuel A Pouchon, and Metin Yetisir</i>	512
Lead Cooled Fast Reactors <i>Alessandro Alemberti</i>	523
Gas Cooled Fast Reactor System (GFR) <i>Branislav Hatala</i>	545
Molten Salt Reactors <i>Victor V Ignatiev</i>	553
Super-Critical Water-Cooled Reactor (SCWR) <i>Yanping Huang, Jinguang Zang, and Laurence Kim-Hung Leung</i>	569
Advanced Light Water-Cooled Reactor Concepts <i>Eugene Shwageraus</i>	582

Fluoride-Salt-Cooled High-Temperature Reactors <i>Massimiliano Fratoni</i>	602
Introduction to Breed and Burn Reactors <i>Staffan Qvist</i>	609
Molten Chloride Fast Reactors (MCFRs) <i>Jiri Krepel and Kevin J Kramer</i>	625
Traveling Wave Reactor (TWR [®]) <i>Pavel Hejzlar</i>	643
CANDLE Reactor Concept <i>Hiroshi Sekimoto</i>	657
A Seed-Driven Breed-and-Burn Blanket Core Concept <i>E Greenspan</i>	673
Worldwide Status of Small Reactors Research and Technology Development <i>Frederik Reitsma and M Hadid Subki</i>	685
Water Cooled Small Modular Reactors (Integral PWR and BWR) <i>M Hadid Subki</i>	694
Floating Nuclear Power Plants With Small Modular Reactors <i>M Hadid Subki</i>	711
Pebble Bed Gas Cooled Reactors <i>Frederik Reitsma</i>	721
Heavy Liquid Metal (HLM) Cooled Fast Small Modular Reactors <i>Craig F Smith</i>	732
Micro-Reactors <i>Janne Wallenius</i>	749
Light Water Reactors (LWR) Fuel Cycle Options <i>Eugene Shwageraus</i>	757
Advanced Fuel Cycles Identification and Evaluation <i>R Wigeland, T Taiwo, M Todosow, W Halsey, and J Gehin</i>	771
Self-Sustaining Breeding in Advanced Reactors: Characterization of Natural Resources <i>Jiri Krepel</i>	786
Self-Sustaining Breeding in Advanced Reactors: Characterization of Selected Reactors <i>Jiri Krepel and Evzen Losa</i>	801
Self-Sustaining Breeding in Advanced Reactors: Comparison of Fuel Cycle Performance <i>Jiri Krepel</i>	820
Advanced Modeling and Simulation Methods <i>Carlo Fiorina</i>	837
Additive Manufacturing in the Nuclear Reactor Industry <i>Benjamin R Betzler</i>	851
New Reactor Concepts Deployment Challenges and Opportunities <i>Ramesh Sadhankar</i>	864

VOLUME 2

Safety, Licensing and Decommissioning of Power Reactors

Safety, Regulation, and Decommissioning of Commercial Nuclear Power Reactors—Introduction <i>Joy L Rempe</i>	1
Safety Lessons From Two Events Without Core Damage <i>Joy L Rempe</i>	6
The Three Mile Island Unit 2 Accident <i>Gordon R Skillman and Joy L Rempe</i>	17
The Chernobyl Nuclear Power Plant Unit-4 Accident <i>Alexander R Sich</i>	30
The Events at Fukushima Daiichi <i>Shinya Mizokami and Joy L Rempe</i>	53
Ensuring Safety by Design and Evaluation <i>Joy L Rempe</i>	67
Reactor Protection System <i>Robert Lutz and Bill Williamson</i>	76
Engineered Safety Features <i>Robert Lutz and Bill Williamson</i>	88
Instrumentation and Control <i>Robert Lutz and Bill Williamson</i>	99
Guidance for Operating Within Design Basis Conditions <i>Robert Lutz and Bill Williamson</i>	108
Beyond Design Basis Event Considerations <i>Robert Lutz and Bill Williamson</i>	115
Safety Evaluations <i>RO Gauntt</i>	126
Overview of Nuclear Regulation and Regulatory Framework <i>Joy L Rempe and Laurence G Williams</i>	139
U.S. Regulation and Licensing—Historical Perspective <i>Dennis C Bley and Marty Malsch</i>	150
U.S. Regulations for Commercial Nuclear Power Plants <i>Dennis C Bley and Marty Malsch</i>	163
U.S. Options for Licensing a New Commercial Power Plant <i>Harold B Ray</i>	168
Regulation of Two U.S. Non-LWRs—Lessons Learned <i>Joy L Rempe</i>	175
Overview of International Nuclear Safety Regulation and Licensing <i>Laurence G Williams</i>	188
Probabilistic Risk Assessment <i>Mohammad Modarres and Inn Seock Kim</i>	207

Regulatory Applications of Risk Assessment <i>Donald A Dube</i>	218
Risk Assessment Insights and Impact <i>Karl N Fleming</i>	227
Nuclear Power Plant Decommissioning <i>Rod McCullum</i>	240
SAFSTOR Decommissioning Example (Kewaunee) <i>Rod McCullum</i>	247
DECON Decommissioning Example (Maine Yankee) <i>Rod McCullum</i>	251
The Nuclear Fuel and Fuel Cycle	
Introduction to Fuel Cycle Front End: From Mining Through Utilization <i>Douglas C Crawford</i>	255
Uranium Resources <i>Ian Hore-Lacy</i>	265
Uranium Extraction From Seawater Makes Nuclear Power Virtually Renewable <i>James L Conca</i>	277
Unconventional Uranium Resources From Phosphates <i>Nils H Haneklaus</i>	286
Uranium Conversion and Enrichment <i>Patrick Hogan</i>	292
Fuel Design and Fabrication: Pellet-Type Fuel <i>Masato Kato</i>	298
Fuel Design and Fabrication: Fast-Reactor Metal Fuels <i>Douglas L Porter and Douglas C Crawford</i>	308
Fuel Design and Fabrication: TRISO Particle Fuel <i>Grant W Helmreich and John D Hunn</i>	318
Fuel Design and Fabrication: Research Reactor Fuel <i>James I Cole, Jan-Fong Jue, and Glenn A Moore</i>	326
Nuclear Criticality Safety <i>Douglas G Bowen</i>	334
Fresh Fuel Properties: Ceramic Compounds <i>Giovanni Pastore and Aysenur Toptan</i>	343
Zr-Alloyed Metallic Fuel Properties <i>Stephen Novascone, Christopher Matthews, Albert Casagrande, Aysenur Toptan, and Adam Zabriskie</i>	356
Molten Salt Fuels: Properties, Purification, and Corrosion Control <i>Ruchi Gakhar, William C Phillips, Guoping Cao, Tae-Sic Yoo, Michael E Woods, Guy L Fredrickson, and Toni Karlsson</i>	366
Irradiation Performance: Light Water Reactor Fuels <i>Paul Cantownine and Bob Rand</i>	377

Irradiation Performance: Fast Reactor Fuels <i>Colby B Jensen and Nicolas E Woolstenhulme</i>	392
Irradiation Performance: High-Temperature Gas Reactor Fuels <i>Tyler J Gerczak</i>	407
Irradiation Performance: Research Reactor Fuels <i>James I Cole, Hakan Ozaltun, Jan-Fong Jue, Warren F Jones, Dennis D Keiser, Jr, Barry Rabin, and Mitchell K Meyer</i>	420
The Nuclear Waste and its Disposal	
Key Characteristics of Used Nuclear Fuel <i>J-P Glatz</i>	429
Fuel Storage (New Fuel/Used Fuel Pool) <i>John H Kessler</i>	441
The Chemical Basis for Separating Recycling Materials by Hydro-Processes <i>Robin Taylor</i>	450
The Chemical Basis for Separating Recycling Materials by Pyro-Processes <i>Stéphane Bourg</i>	465
The Current Industrial Mono-Recycling of U and Pu: Reprocessing Step <i>Gérald Senentz</i>	482
The Current Industrial Mono-Recycling of U and Pu: Recycling Step <i>Jean-Michel Marin</i>	494
Routes for Pu Multi-recycling <i>Bernard Boullis and Christine Chabert</i>	510
The Adaptation of Recycling Processes to Pu-Multi Recycling <i>Manuel Miguiriditchian and Robin Taylor</i>	523
Effluent Decontamination <i>V Blet</i>	534
ILW conditioning and performance <i>Samuel A Walling, Laura J Gardner, and Neil C Hyatt</i>	548
HLW Conditioning and Long-Term Performance <i>Florence Bart, Christophe Poinssot, Stéphane Gin, Sylvain Peuget, and Céline Roussel</i>	564
Spent nuclear fuel long term behavior and performance <i>Bernd Grambow</i>	577
The Concept of Geological Disposal of Highly Radioactive Nuclear Waste <i>Rodney C Ewing and Sulgiye Park</i>	588
Radionuclide Migration in the Context of High-Level Nuclear Waste Management <i>Jordi Bruno</i>	603
Main Repository Projects Worldwide <i>Soufiane Mekki</i>	616
Actinide Immobilization in Dedicated Wasteforms: An Alternative Pathway for the Long-Term Management of Existing Actinide Stockpiles <i>Lewis R Blackburn and Neil C Hyatt</i>	650

Potential Fuel Cycle Back-End for Thorium Fuel Cycle <i>Xiangzhou Cai and Zhiguang Wang</i>	663
Assessment of the Relative Environmental Footprint of Nuclear Energy and Its Fuel Cycle <i>Ch Poinssot and S Bourg</i>	675
Social Acceptability of Geologic Disposal <i>Daniel S Metlay</i>	684
Radiation Protection	
Radiation Protection – Introduction <i>Laurence Miller</i>	698
Ionizing Radiation: Discovery and Dose Quantities <i>Shaheen Azim Dewji</i>	701
Fundamentals of Health Physics <i>Shaheen Azim Dewji and Laurence Miller</i>	716
Natural and Man-Made Sources of Radiation <i>Laurence Miller, A Iulian Apostoaei, Michael Howard, and Vikram Singh</i>	744
Source Terms for Nuclear Reactors Operations, Accidents, and Waste <i>Vikram Singh and Alexander M Wheeler</i>	765
External Dosimetry <i>Ken G Veinot</i>	777
Internal Dosimetry <i>Lisa M Snapp and Keith F Eckerman</i>	790
Instrumentation and Practices for Radiological Assessments <i>Timothy J Vitkus, David A King, Nick A Altic, and Wade P Ivey</i>	803
Emergency Response <i>Craig M Marianno</i>	828
Standards to Control Radiation Exposures of Workers and the Public <i>David C. Kocher</i>	840
Risk Tradeoff Analysis <i>TW Hansen, Jr</i>	851
Computer Codes for Determining Acceptable Levels of Contamination <i>John Arnish</i>	858
Characterization and Release of Contaminated Sites <i>Timothy J Vitkus</i>	869
Radiological Control Practices <i>TW Hansen, Jr</i>	890
Radiation Shielding Methods <i>Ronald Pevey</i>	899
Shielding Against Galactic and Solar Radiation in Space <i>Lawrence Heilbronn</i>	914
Health Effects and Radiation Biology <i>Trent L Nichols and Thomas Byrne</i>	923

Estimation of Health Risks From Exposure to Ionizing Radiation <i>A Iulian Apostoaei</i>	937
Drones for Radiological Assessment <i>Alexandra C Hackett</i>	950
An Illustrative Example of Microdosimetry—Boron Neutron Capture Therapy for Cancer <i>Trent L Nichols</i>	958
Radiation Protection: Glossary of Terms <i>Shaheen Azim Dewji, David C Kocher, and Sherry Adadi</i>	981

VOLUME 3

Non-Electric Applications of Terrestrial Nuclear Reactors

Introduction to Nonelectric Applications of Nuclear Energy <i>Shannon M Bragg-Sitton and Richard D Boardman</i>	1
District Heating and Nuclear Power <i>AE Schweikert and MR Deinert</i>	8
Nuclear Driven Water Desalination <i>Aaron S Epiney, Konor L Frick, Cristian Rabiti, Jeffrey Brown, and Shannon M Bragg-Sitton</i>	17
Nuclear-Supported Electrification of the Transportation Sector <i>Xinyu Liu, Adarsh Bafana, Pingping Sun, and Amgad Elgowainy</i>	25
Heat Pumps Driven by Zero-Carbon Electricity <i>J Stephen Herring</i>	34
Coupling Heat Storage to Base-Load Nuclear Reactors for Variable Heat, Electricity and Hydrogen <i>Charles W Forsberg</i>	40
Process Heat for Chemical Industry <i>Richard D Boardman, Michael G McKellar, Brian D Dold, Andrew W Foss, and Haydn C Bryan</i>	49
Industrial Processes for Grid Stabilization <i>Frédéric Bienvenu</i>	61
Thermochemical Hydrogen Production <i>Sellathurai(Sam) Suppiah</i>	73
High Temperature Steam Electrolysis <i>Richard D Boardman</i>	82
Synthetic Hydrocarbon Fuels From H ₂ and Captured CO ₂ <i>Lesley Snowden-Swan, Shuyun Li, Jeromy Jenks, Steven Phillips, Jalal Askander, Jamie Holladay, L Todd Knighton, and Daniel S Wendt</i>	94
Ammonia Synthesis <i>Richard D Boardman</i>	113
Hydrogen-Based Flash Ironmaking Technology (HyFIT): A Novel Green Ironmaking Technology With Low Energy Consumption <i>Hong Yong Sohn</i>	122

Calcination	131
<i>Nils H Haneklaus</i>

Introduction

To appreciate the wide variety of reactors considered to be research reactors requires an understanding of the history and the categorization of these reactors. The categorization is important to differentiate research or testing reactors from demonstration, prototype, propulsion, or power reactors. Globally, over 600 research reactors have operated and contributed to the fields of nuclear engineering and science over the more than 70 years since the first sustained chain reaction ([IAEA Research Reactor Database, 2018](#)). A broad historical survey of all research reactors built would be interesting but many of the reactors constructed in the past were superseded quickly by more advanced designs or were simply research dead ends that did not progress. This chapter does not attempt to describe each of those facilities as many have been shut down or decommissioned with only about 200 research reactors operating today. However, many of the world's currently operating research reactors are based on early research reactors or are essentially the same design sold or provided by companies or governments worldwide in the 1950s and 1960s (e.g., TRIGA, IRT, or VVR reactors).

In several cases, application or test environment specific reactors were built that are unique and continue to be operated today. Many reactors designed and operated during the early years of nuclear energy development were specifically used to demonstrate various reactor concepts. In some ways this is a gray area in the definition of research reactors and many of these would be better classified as demonstration or experimental reactors. For example, reactors that demonstrated liquid metal and molten salt coolants or nuclear power production in a boiling water reactor would not be considered true research reactors. However, there are liquid metal cooled fast spectrum reactors currently operating, under construction, or being considered that would be used to test materials for deployment in fast spectrum power reactors that would be classified as research or test reactors.

Today, the utilization of research reactors has matured, and many research reactors designed to be multi-purpose have generally focused on key research or utilization strengths. Research reactors continue to be important to nuclear science and engineering education with many graduate students that were trained on a university reactor going on to perform advanced research using the limited number of high-performance reactors in the world. Research reactors operating at powers of tens of megawatts have sufficient flux for the efficient production of medical radioisotopes in addition to the research activities of the facility. The value of small research reactors as an important educational tool for the public and students cannot be underestimated. University research reactors are essential for demonstrating nuclear physics and reactor operations as an entry into the nuclear science and engineering field.

First research reactors and development during World War II

The first reactor was used to prove that a controlled nuclear chain reaction was possible. After much preparation, Chicago Pile 1 (CP-1) achieved the first criticality of a man-made nuclear reactor (a natural critical chain reaction occurred at the Oklo site in Gabon, Africa almost 2 billion years ago) on December 2, 1942. This remarkable achievement was led by Enrico Fermi and occurred in a large room, a squash court, under the Stagg Field Stadium at the University of Chicago. The pile, as it was called, consisted of stacked blocks of graphite with natural uranium slugs in holes drilled into the graphite. The stack was made in the approximate shape of a sphere and only operated for a few minutes for that first experiment before Fermi ordered the insertion of a cadmium control rod to stop the chain reaction and shutdown CP-1. The reactor was used for initial experiments but could only operate to a maximum level of 200 W to minimize radiation exposure to researchers from the unshielded nuclear reactor. CP-1 ceased operation on February 28, 1943 to dismantle it and move the reactor out of the city for further experiments ([American Nuclear Society, 1992](#)).

The reactor was moved in 1943 to a building called Site A, in an area of the Argonne Woods outside of Chicago. This was to have been the originally proposed location for the first criticality experiment, but the building was still under construction in 1942. The

reconstructed reactor was now called CP-2 and was reconfigured to be more block-like and surrounded by 1.5 m of concrete for shielding, except for the top which was primarily lead and wood (Fig. 1 below). CP-2 was large, about 9 m wide and long and 6 m high. The reactor contained 52 tons of natural uranium and was air-cooled. Heating of the graphite was a problem and the CP-2's normal maximum power level was 1 kW, but it occasionally was operated to 5 kW or 10 kW for short periods for specific experiments. CP-2 should be considered the first true research reactor with an extensive experimental program measuring reactivities of various materials as well as the reactor's operating characteristics. The early experimental program supported the development of later reactors designed to support the war effort to produce plutonium but CP-2 continued to operate until 1954.

The X-10 reactor was constructed at the Clinton site near Oak Ridge, Tennessee and started up on November 4, 1943. The X-10 was based on the CP-2 and was originally designed to be a prototype or pilot plant for the plutonium production reactors to be built at the site near Hanford, Washington. The X-10 was air-cooled by large blowers and could operate up to 4 MW. The X-10 was built as a demonstration facility and was used to produce small amounts of plutonium and for research developing the separation chemistry needed for the materials expected to come from the production reactors. Another important use of the X-10 was as a training platform for the operators and engineers who would be needed to operate and maintain the reactors at Hanford that were under construction. The X-10 operated for research purposes until 1963. The Belgian BR-1 reactor located in Mol, Belgium started up in 1956 and is very similar in design to the X-10 reactor. The BR-1 continues to operate today for research and education with a maximum power of 4 MW.

The CP-3 (shown in Fig. 2 below) reactor was designed and built at the Argonne site near CP-2 under the direction of Walter Zinn as an alternative to the graphite-natural uranium reactor for plutonium production. This reactor used heavy water, D_2O , as the moderating material and started up on May 15, 1944. As the heavy water was a more efficient moderator and reflector, CP-3 was much smaller than the CP-2 reactor. Being more compact, the average neutron flux in CP-3 was much higher for a given power than the graphite-natural uranium reactors. The later Canadian ZEEP (Zero Energy Experimental Pile) and NRX (National Research Experimental) reactors were of this design although NRX was light water cooled. The JEEP (Joint (Norwegian-Dutch) Establishment for Nuclear Energy) reactor which operated (critical in 1951) at Kjeller, Norway was very similar to the CP-3.

The final type of research reactor constructed and operated during World War II was the Water Boiler reactor which was a homogeneous mixture of enriched uranyl sulfate and light water operated at the Los Alamos site. The reactors were operated below the actual boiling point of water but the bubbles produced from radiolysis made them appear to be boiling. The first reactor of this design started up on May 9, 1944 and was called LOPO (Low Power) because it operated at less than 1 W. This reactor provided valuable information to improve critical mass calculations for the nuclear bomb design. LOPO only operated for a few months before it was reconfigured in December 1944 as HYPO (High Power) and began operation to a maximum power of 5.5 kW fueled by enriched uranyl nitrate in light water. A version of HYPO was the first research reactor to operate in the United States outside the U.S. government and the first civilian licensed research reactor and began operation in 1953 at what is now known as North Carolina State University.

Fig. 2 CP-3 operating in 1944.

Post-War research reactor development and activities

In the years from 1946 to 1954 there was great interest in expanding the use of nuclear reactors as a research instrument and the production of propulsion power and electricity from steam generated by the heat of nuclear fission. The use of fissile materials was strictly controlled by the government and much of the research was classified at the time. During this period, some of the higher power reactors were used to demonstrate liquid metal cooled fast spectrum reactors (Experimental Breeder Reactor-1, EBR-1) and the possibilities of operating submarines using nuclear power (Submarine Thermal Reactor, STR). These demonstration or prototype reactors were important to show engineering scale-up of concepts but are not considered true research reactors as they were built for a single purpose with very little flexibility for experimentation.

Canadian scientists had participated in many early experiments using the CP-2 and CP-3 reactors during and immediately after World War II. The National Research Experimental (NRX) reactor located at Chalk River in Ontario started up in August 1947. The NRX was based upon the CP-3 design and initially operated at 10 MW fueled by natural uranium, cooled by light-water, and neutron moderated by heavy water surrounding the fuel elements. For a time, it was the most intense neutron source in the world. The NRX suffered an operator-initiated accident in December 1952 which caused a rapid power transient and a cladding rupture of several fuel rods in the reactor. Lessons learned from that accident concerning reactor safety and redundant protection systems were applied towards future reactor designs. The NRX core was replaced and the reactor power was raised to 42 MW in 1954. A later Canadian-designed research reactor, the National Research Universal (NRU), began operation in 1957 fueled with natural uranium and operating at 200 MW. The NRU was converted to enriched uranium in 1964 and eventually operated using low-enriched uranium fuel at 135 MW before it was permanently shutdown in 2018.

The CP-3 reactor operated for experiments until 1950 when the fuel was then removed due to suspected corrosion of the aluminum cladding around the fuel rods. The reactor was upgraded and redesigned using enriched uranium fuel and restarted as CP-3' (CP-3 Prime) in May 1950. CP-3' was shutdown permanently 4 years later on the same day as the CP-2 shutdown. CP-3' was replaced by the CP-5 reactor at the Argonne National Laboratory in 1954 and Site A was decommissioned. The CP-5 research reactor was based upon the CP-3' design and was also a heavy-water reactor with enriched uranium fuel. CP-5 operated at a power of 5 MW and was used as a strong neutron source for materials irradiations and to create neutron beams. The CP-5 reactor design was later used as a model for many research reactors that used heavy water coolant built around the world (e.g., NBSR in the US, DIDO in the UK, and HIFAR in Australia).

It was identified very early on while testing in CP-2, CP-3, and the higher power production reactors that materials exposed for a long time to intense neutron and gamma radiation could change physical properties. In 1944, work had begun at the Clinton Laboratories near Oak Ridge, Tennessee to design a high flux reactor that could be used to test materials that would potentially be used in later reactor designs. The project was approved in 1946 but the U.S. Atomic Energy Commission decided in 1949 that the 30 MW reactor should be built in a remote area near Arco, Idaho. The Materials Testing Reactor (MTR) was fueled by highly enriched (93%) uranium and cooled and moderated by light water. Beryllium and graphite were used as neutron reflectors. The MTR went critical on March 31, 1952 and was the highest flux research reactor for many years. The MTR power was eventually raised to 40 MW in 1955 with an average thermal neutron flux of 3×10^{14} neutrons/cm²/s. The MTR was designed to be a flexible testing reactor and had over 100 irradiation facilities and six horizontal neutron beam tubes. The MTR fuel was designed to produce a more

compact reactor by using plate fuel rather than pins or slugs. The high thermal conductivity of the flat plates permitted higher power densities and the resultant high neutron densities while still being sufficiently cooled. The MTR fuel plates were an aluminum-uranium mixture clad in a “sandwich” of aluminum cladding. The fuel development was led by Eugene Wigner at the Clinton Laboratories (Rosenthal, 2010). This fuel was so robust and useful that the basic design was used for many reactors constructed world-wide and became universally known as “MTR-type” reactor fuel. Prior to MTR’s construction, the reactor vessel and piping were mocked-up at Oak Ridge facilities to perform mechanical and hydraulic testing of the MTR cooling system design before it was constructed. In 1950, fuel and beryllium were loaded into the vessel to perform low-power reactor physics testing to evaluate and improve the neutronic design of MTR prior to its initial criticality. The reactor was called the Low-Intensity Test Reactor (LITR) and was eventually modified and improved to operate up to 3 MW.

As nuclear power and propulsion reactor programs advanced there was a need to evaluate how to shield the intense gamma and neutron radiation produced from the operating reactors. Materials inserted into or irradiated by reactors had provided information on nuclear cross-sections and radiation effects but could not provide a test platform to evaluate new radiation shielding materials. The Bulk Shielding Reactor (BSR), built at ORNL, used the MTR-type fuel and was constructed in a large tank or pool of light water (6 m by 12 m and 7 m deep) to provide flexible access and insertion of large radiation shield prototypes. The BSR (Fig. 3 below) went critical in December 1950 and initially operated up to 100 kW on natural circulation cooling. A down-flow forced cooling system was later installed that allowed operation up to 2 MW. The BSR design was low cost to construct and was often called a “swimming pool reactor.” The fundamental BSR design was used in dozens of research reactors worldwide because it was inexpensive to construct and relatively easy to operate.

On December 8, 1953, U.S. President Dwight D. Eisenhower gave his famous “Atoms for Peace” speech at the UN General Assembly which helped establish the International Atomic Energy Agency (IAEA) in 1957. His speech and the 1955 International Conference on the Peaceful Uses of Atomic Energy in Geneva propelled the rapid growth of peaceful nuclear research around the world and the accelerated design and deployment of research reactors over the next two decades. The number of research reactors operating globally in 55 countries peaked around 1975. Most of the research reactors operating today are over 50 years old so there are ongoing efforts to maintain and upgrade these facilities when possible. In several cases, countries with highly utilized research reactors are planning to build replacement facilities that are designed with advanced safety features and enhanced utilization facilities.

Research reactor design approaches

Research reactors are fundamentally neutron sources, but some operate at such low powers (less than 1 W) that they are called zero-power or critical facilities. A key differentiator of research nuclear reactors from other reactors is whether the heat of the fuel is used

Fig. 3 ORNL bulk shielding reactor (1950).

to generate steam. The steam may be then used to generate electricity or provide propulsion. There have been nuclear thermal rockets designed and tested for propulsion using high temperature gases, but these would still not be classified as research reactors. The use of the research reactor is somewhat related to the intensity of the neutron flux in the reactor core. There is a significant variety in the design of research reactors. The following provide the scope for possible design approaches when designing research reactors:

- Fuel materials: U-Al alloy; Uranium silicide U_3Si_2 ; Uranium-Zirconium hydride UZrH_x (x is typically 1.6); Uranium dioxide UO_2 ; metallic uranium. UZrH_x is being used exclusively in TRIGA-type research reactors; its unique feature is that it provides a strong negative reactivity feedback upon fuel temperature increase that enables operating TRIGA reactors in a pulsed mode. U_3Si_2 has been used as a substitute for U-Al dispersion fuels and alloys when converting some reactors to operate with less than 20% enriched uranium rather than with HEU.
- Uranium enrichment: Highly enriched uranium HEU—had been a common fuel in many research reactors; Low enriched uranium (LEU)—up to 20% of ^{235}U —the common fuel in most contemporary research reactors; Natural uranium—feasible only in heavy-water moderated research reactors.
- Fuel element geometry: plate type fuel or fuel rods.
- Moderator type: Regular water H_2O ; heavy water D_2O . Most research reactors use H_2O moderators.
- Coolant type: Most research reactors use H_2O but some use D_2O for coolant.
- Reflector type: Most research reactors use H_2O reflector but D_2O cooled reactors use D_2O for reflector as well. Some H_2O cooled research reactors use beryllium or D_2O reflectors. Since the probability of neutron absorption in D_2O and in Be is significantly smaller than in H_2O , the use of D_2O or Be enables to have a higher thermal neutron flux in various experimental facilities in and around the core.
- Cooling mode: Most research reactors use natural coolant circulation for removing the energy released by fissions. High flux reactors usually use forced circulation cooling.
- Core containment: Most research reactors use open water pools with the core installed near the bottom. Heavy-water moderated contain the core in a closed vessel. High flux research reactors use a closed reactor vessel with forced circulation water coolant/moderator.
- Designed for high thermal neutron flux: The neutron flux level is directly proportional to the power generated per unit fuel volume (power density) and inversely proportional to the fissile fuel concentration per unit fuel volume. The power density can be maximized in two ways: (1) By maximizing the ratio of the fuel surface area in contact with the coolant to fuel volume; that is, by using plate-type fuel. (2) By maximizing the heat flux from the fuel to the coolant; that is, by using forced circulation cooling.
- Maximized neutron flux to core power ratio: As the primary product of many research reactors is the neutron flux available for multitude of experiment, it is desirable to minimize the reactor power for a given neutron flux level; a higher power implies higher rate of fuel consumption and more expensive heat removal systems. This objective can be achieved by minimizing the outer core surface area. The most compact critical core using fuel with a given enrichment can be achieved using water moderator and beryllium or heavy-water reflector. Using heavy water moderator enables designing research reactors that are fueled with natural rather than enriched uranium but the minimum core volume of such reactors is much larger than that of a light-water cooled reactors; the latter must use, though, enriched uranium fuel. Increasing the enrichment of the fuel will minimize the parasitic absorption by uranium-238 and other core materials which will enable a smaller core volume.

Low-power, low-flux reactors operating at universities are used for teaching fundamentals of reactor physics and operations but are often also used for neutron activation of materials for testing and analysis in student research projects. Higher power research reactors enable more complicated experiments that require higher neutron intensities. These higher flux reactors produce most of the world's industrial and medical radioisotopes. Lower power (< 5 MW) research reactors may have horizontal neutron beam tubes but the beam intensity is relatively low for high quality neutron scattering experiments with a low signal to noise ratio. The highest thermal flux reactors operating today can only achieve approximately 10^{15} neutrons/cm²-sec flux levels due to cooling limits for higher power densities.

Categories of research reactors

There are many ways to categorize research reactors (fuel, coolant, moderator, etc.) but the function or utilization of the reactor is generally related to the power level and neutron flux available ([International Atomic Energy Agency, 2016](#)). The lowest powered research reactors operate at “just critical or near-critical” with minimal thermal power (generally less than 1 W) generated. These critical assemblies or zero-power reactors are reconfigurable to test different reactor designs, fuels, or moderators, and benchmark computational models. Some universities have these reactors and use them for teaching reactor operations and performing reactor physics laboratories. In the last decade, neutron producing particle accelerators have been coupled to some of these facilities to evaluate models for accelerator-driven subcritical systems (ADSS) that could be used to transmute or “burn” high level nuclear waste. The design of most of these zero-power reactors allows precise control of reactor physics measurements to confirm models. These reactors are not used for irradiation experiments because of the very low neutron flux available.

One such low power research reactor that would be used more for training of engineers and scientists is the Argonaut reactor. The name is actually an acronym for ARGOnne Nuclear Assembly for University Training. The first Argonaut went critical in February 1957 and operated at 10 kW. The reactor was used to teach reactor theory and physics and operated at Argonne National Laboratory (ANL) until 1972. The reactor was not decommissioned at that time but was dismantled and shipped to Taiwan to become a training

platform for that country. A second Argonaut was built specifically for the second International Conference on the Peaceful Uses of Atomic Energy in 1958. The reactor was assembled for conference attendees, brought to criticality at the conference, and then dismantled and shipped back to ANL. There only a few Argonaut reactors still operating but one is actively used today for teaching students at the University of Florida.

Another research reactor that was designed specifically as a training platform are the AGN-201 reactors. These reactors were designed and built by Aerojet-General Nucleonics in the late 1950s. The AGN-201 is factory manufactured, relatively portable, homogenous, thermal reactor. The reactor core is unusual because it composed of a stacked series of circular disks composed of a mixture of polyethylene and uranium oxide (19.75% enriched). A horizontal tube passes through the reactor to allow irradiation and activation of materials for experiments. A maximum power level of less than 5 W limits the level of experimentation to nuclear engineering classes or laboratories. Many universities and colleges used these small reactors in the 1960s and 1970s but most have been decommissioned. There a few AGN-201 reactors still operating around the world. Three university programs that actively use the AGN-201 reactor for teaching are at Idaho State University, New Mexico State University, and Texas A&M University.

The next level of research reactor type and use would fall under a category of education and research reactors. These reactors operate from roughly 5 W to 5 MW and are often associated with a university nuclear education program. Reactors built for university research are often a pool-type reactor with horizontal beam tubes for maximum access and use of the reactor for irradiation experiments. Because the highest neutron flux intensity would be found in the reactor interior, special irradiation locations or pneumatic systems may be designed to utilize this higher flux. Thermal neutrons leaking from the core may be put to use by collimation in a horizontal guide tube and creating a neutron beam. Such beams may be used for neutron radiography or cross-section measurements. The lower neutron flux available in the areas external to the reactor core and in the beams usually require longer irradiation times to compensate and provide sufficient fluence or counting data. Research reactors include the pulsing or transient reactors which operate at relatively low steady-state powers but are able to rapidly raise reactor power for high-power (> 1200 MW) transients that last less than 1 s.

The final grouping or category of research reactors would be considered to be the high-performance research reactors. These reactors were originally designed to provide intense neutron fluxes for irradiation testing of materials or radioisotope production. Many of these facilities were also designed with numerous neutron beam ports which have enabled great advances in neutron scattering science. Unlike lower power facilities at most universities or many research centers, the high-performance research and testing reactors will usually operate 24 h a day over several shifts. These larger research reactors were usually constructed as the main facility of a multidisciplinary nuclear laboratory. Ancillary facilities supporting the reactor may include hot cells for examining irradiated materials and radiochemistry laboratories.

Fuel conversion of operating research reactors

The 1954 Atoms for Peace Program encouraged the export of research reactors to many other countries to support the development of peaceful uses of nuclear materials. Many of the early exported research reactors utilized low-enriched ($< 20\%$) uranium (LEU) or natural uranium fuels. However, these fuels limited research reactor capabilities, so the United States and the Soviet Union began to export reactors and reactor fuels utilizing highly enriched uranium (HEU). In 1978, an international effort lead by the United States to reduce the civilian use of HEU in research reactors worldwide was created. This was called the Reduced Enrichment for Research and Test Reactors Program (RERTR) which had an initial goal to convert as many higher powered (> 1 MW) research reactors as possible to LEU fuels. While many low-powered research reactors were relatively straight-forward to convert to LEU fuels without reducing the research capabilities, other research reactors were more challenging to convert. Higher powered and higher flux reactors were designed to operate with the higher U-235 densities of HEU. These fuels had already reached the uranium concentration limits of the current technologies available at the time. Under RERTR, a fuels development program was initiated that could allow conversion of the higher performance reactors without a loss of research capability. Early successes included the qualification of an LEU silicide-aluminum dispersion plate fuel in 1988. This fuel achieved uranium densities up to 4.8 g/cm^3 which allowed the conversion of a number of research reactors that could not convert previously ([U.S. Nuclear Regulatory Commission, 1988](#)). A high density, LEU TRIGA fuel that achieved 45-wt% was qualified and accepted in 1987 and permitted conversion of all U.S. TRIGA reactors from HEU FLIP (Fuel Life Improvement Program) fuels ([U.S. Nuclear Regulatory Commission, 1987](#)).

In 2004, the U.S. Department of Energy and National Nuclear Security Agency (NNSA) started a new program, the Global Threat Reduction Initiative (GTRI), that would continue to support the original RERTR goals but would now include efforts to address nuclear and radioactive material security and control. The GTRI program transitioned to become the Materials Management and Minimization (M3) program within NNSA. The M3 program compliments and supports LEU fuel development and conversion efforts in the European Union (under EURATOM), the International Atomic Energy Agency (IAEA), and the Russian activities (Rosatom). As of 2019, several potential high-density LEU fuels are under development that could allow the conversion of operating high-performance research reactors and become potential fuels for next generation research reactors.

Regulation and safety of research reactors

Each country that uses nuclear materials, radiation, or operates a nuclear reactor of any kind is expected to develop methods or laws that will regulate the use of nuclear materials and the resulting byproducts to ensure the safety of the public. The International

Atomic Energy Agency (IAEA) was not created to regulate the use of nuclear materials in member countries. The IAEA's purpose is to promote the peaceful and safe use of nuclear energy science and technology, and to inhibit its use for any military purpose, including nuclear weapons. There are currently 171 IAEA member states and while some of these countries have operating nuclear power plants, many more of the member states only operate research reactors for education and research and are only planning a nuclear power program. The IAEA supports the member states regulatory bodies and provides training and coordination to ensure a reasonable level of nuclear safety is maintained.

Because research reactors operate at lower powers, have a lower fission product inventory and lower cooling requirements after shutdown they are considered lower risk facilities as compared to nuclear power plants. Many countries that have both operating nuclear power plants and research reactors apply a graded approach to regulation and oversight due to the lower risk to the public and the environment. The IAEA works to harmonize regulation of research reactors and their applications across all member states by providing workshops, support missions, and documents generated from multi-country work groups.

Introduction

Research reactors (RRs) contribute to improve the health of people, to combat climate change, to develop the materials that will underpin the technologies of the future, to educate the new generations of professionals in nuclear science and technology and in many other fields, to generate new knowledge for humanity, and to enhance prosperity and development of society ([International Atomic Energy Agency, 2014a](#)).

Millions of people benefit from diagnosis and treatment of health disorders with radioisotopes produced in RRs. RRs have been essential in developments in nuclear power, and are used for research and development of other energy sources such as hydrogen cells and batteries. Materials irradiated at RRs as part of their development are present in numerous devices and technologies. Elemental analyses with neutrons contribute to archaeological and cultural heritage studies, to forensics and food safety, to study air quality and the environment, to industrial applications in mining, forest and oil industries. Neutron beams enable leading edge scientific research and non-destructive materials characterization and testing in nearly every area of application including microelectronics, aerospace industry, soft and biological matter, astrophysics and innovative medical techniques.

The number of RRs and their main applications and countries involved are shown in [Table 1](#), as reported in the International Atomic Energy Agency (IAEA) RR database ([International Atomic Energy Agency, n.d.-a](#)). Not all RRs can implement all these applications, as some require certain neutron flux levels ([Table 2](#); [International Atomic Energy Agency, 2014a](#)), specific design features and supporting infrastructure ([International Atomic Energy Agency, 2007a](#)). A RR of a given power level will likely not engage in all possible applications, but will choose those for which it finds users and customers ([International Atomic Energy Agency, 2013a](#)). Such decisions should be underpinned by an effective and achievable strategic plan for utilization ([International Atomic Energy Agency, 2017a](#)), to support the long term sustainability of the RR facility in a changing world.

Education and training

Lectures and courses at universities and professional training courses in nuclear sciences and technologies are often complemented by practical experiments at RRs. Around two thirds of operational RRs are engaged in education and training (E&T) (see [Tables 1 and 3](#)), making this the most common application of RRs worldwide. Education concerns activities with students as part of an

Table 1 Number of RRs and countries involved in the different applications of RRs, as reported in the IAEA RRDB ([International Atomic Energy Agency, n.d.-a](#)) in November 2020. NAA includes Prompt Gamma Analysis (PGA). Neutron therapy includes Boron Neutron Capture Therapy (BNCT) and Fast Neutron Therapy (FNT).

academic program for undergraduate and postgraduate degrees. Training concerns activities with professionals for acquisition of specific professional competences and skills. It can address initial training of new staff or retraining of experienced staff, including those from nuclear utilities.

Low power RRs and sub-critical assemblies are often well suited for basic E&T (Boeck et al., 2015). Some university RRs are exclusively dedicated to E&T. Other RRs, often not directly affiliated to a university, offer their experimental facilities, regularly or sporadically for (under)graduate programs or training courses. Medium and high power RRs, primarily involved in provision of commercial product and services, may lack the flexibility of operation required for E&T. Some high flux RRs neutron sources operate as user facilities dedicated to research and development (R&D) with research mainly done by post-graduate students.

Education

Being part of a higher education institution or being located close to one with easy access to students of relevant subjects and courses is per se not sufficient to attract courses and students. RR managers and staff involved in experiments usually need to approach the university departments and propose courses, experiments and research opportunities that are adequate to the curricula and classes already taught. In some cases, RR staff are also appointed as professors.

University RRs are nearly always involved in education at some level (see Table 3). Nearly two thirds of RRs that report activity in education (International Atomic Energy Agency, n.d.-a) are non-university RRs (82 out of 139). This is reduced to around one quarter (7 out of 27) when only RRs that report 100 or more students per year are considered.

RRs are ideally suited to teach nuclear and radiological engineering, radiation protection and related subjects such as radio- and nuclear chemistry, nuclear energy, nuclear safety and security, radioactive waste management, nuclear applications, medical physics, nuclear medicine, etc. Typically, reactor physics and reactor operation experiments, radiation protection and radiation monitoring activities are conducted. The offer can range from a (series of) half-day experiments to an extended experimental course lasting several weeks.

RRs are also often used to teach other engineering studies such as power, electrical, mechanical and other engineering specialities that require, for example, non-destructive testing (NDT). Affiliations with universities allow for introducing the opportunities of neutron-based research and irradiations in applied sciences such as material science, biology, forensic science, environmental and earth sciences, and even humanities such as archaeology, anthropology, cultural heritage, etc. Besides physics, where reactor physics experiments can also be offered, utilization experiments are usually most appropriate for these subjects. Radiation protection is a cross-cutting subject to all (Fig. 1).

Typical reactor physics experiments at RRs include theoretical background, experimental methods, requirements and recommended equipment and safety precautions are described in International Atomic Energy Agency (2014b) and Rataj et al. (2010):

- Measurement of neutron flux spectra
- Measurement of reactor kinetics parameters

Fig. 1 Teaching students at the Czech Technical University VR-1 research reactor. Courtesy of Czech Technical University, Czech Republic.

- Subcritical multiplication and neutron source effects
- Control rod worth measurement and calibration
- Determination of reactivity, shutdown margin and reactor period
- Critical experiment and approach to criticality
- Reactor power calibration
- Power decay and delayed neutron measurements
- Temperature, void and material effects on reactivity.

Reactor operation experiments comprise the above while putting the emphasis on operations and reactor control. Examples of additional experiments are:

- Research reactor operation, including cold start-up to a certain power, stabilization of reactor period, change of power level at different rates, manual and automatic control, shut down, hot restart.
- Reactor instrumentation and control, both for analogue and digital (I&C) systems.

Radiation protection and monitoring experiments take advantage of the RR as a neutron and gamma-ray source and of the availability at the RR of a range of radiation detection and monitoring systems, shielding, irradiated samples, standard sources and personal protective equipment. Many relevant activities and experiments can be performed, including development of emergency scenarios and evacuation drills.

Utilization experiments can be based, in principle, on all experimental activities and R&D at the RR. The latter is often carried out by graduate and post-graduate students under supervision. Utilization experiments commonly offered include:

- NAA for trace element analysis, from sample preparation to irradiation and counting
- Radioisotope production, including preparation and use of radiotracers
- Neutron imaging
- Neutron diffraction, neutron scattering and time-of-flight experiments.

Training

Nearly all non-university RRs involved in E&T report activity in training, compared to only around 70% university RRs (see [Table 3](#)). More non-university than university RRs report training of 20 or more professionals per year.

The nuclear workforce can be divided in three categories ([OECD, 2012](#); [UK Department of Energy and Climate Change, 2015](#)):

- Nuclear: subject matter experts with specialized formal education in nuclear subjects
- Nuclearized: staff with formal education in a non-nuclear area, requiring development of nuclear skills
- Nuclear-aware: staff with generic skills requiring nuclear awareness training.

This categorization was developed for nuclear power. However, training of nuclear power plant staff has been reduced in RRs following the widespread use of reactor simulators by the nuclear energy industry. The categorization can be also used for staff from radiation protection and related professions, regulatory bodies, nuclear safety and security, research reactor operators and users, nuclear applications, etc., taking advantage of the access at the RR to different types and sources of radiation, radiation detection and monitoring systems, and flexibility in the use of the facility.

Training at RRs addresses well-defined training needs of nuclearized or nuclear-aware staff in short duration training courses, from a few days to some weeks (see [section “Education”](#)). It can also be aimed at the development of highly specialized competences for nuclear staff in extended training lasting up to 1 or 2 years, for instance through the IAEA International Centres based on Research Reactors (ICERRs) scheme ([International Atomic Energy Agency, n.d.-b](#)). In these cases, training in specific areas of utilization is also common.

Public tours and visits

Public tours and visits are one form of education. They can be offered to the general public (usually in Open Door Days), high school and university students, and to specific targeted groups such as local or regional decision makers and stakeholders. This can lead to increased support by the public for nuclear science and technologies, including nuclear energy, as it has been shown that people become increasingly supportive of nuclear when they feel better informed and their level of knowledge about the subject is higher ([Nuclear Energy Agency, 2010](#)).

Exposure of high school students to the exciting science, research and development done at RRs can increase their interest in science in general, and in nuclear sciences and technologies in particular. Students often exchange their experience to their colleagues, friends and relatives, with increasing use of school blogs and social media. Such advocacy can lead in the short term to a positive perception of the RR within the community, and more students can become encouraged to choose STEM (science, technology, engineering and mathematics) educational pathways. In the long term, increased awareness of the facility's capabilities may result in expansion of the RR utilization.

Procedures for access control during tours and visits need to be flexible and allow for entrance and movement of groups of people in designated areas of the RR hall, while respecting radiological protection, safety and security requirements, including age limits and constraints for pregnant and breastfeeding women. The tours, conducted by authorized operations staff, are usually preceded by a lecture with technical level adapted to the audience, focusing on the RR purpose, capabilities and contribution to societal goals. The tour can include observing a start-up, viewing the experimental hall, given instruments, the control room, hot cells, and other areas, use of models and mock-ups of the reactor, dummy fuel assemblies and other components. Displays such as posters or digital screens illustrate the work done at the RR and the explanations provided. The visits can also include demonstrations and practical exercises, for instance on radiological protection procedures and radiation detection.

Neutron activation analysis

Neutron Activation Analysis (NAA) is an isotope-specific analytical technique for the qualitative and quantitative measurement of the total masses of major, minor and trace chemical elements present in samples weighting from a few micrograms to several kilograms ([International Atomic Energy Agency, 2001a](#)). The technique is based upon the conversion of stable atomic nuclei into radioactive nuclei by irradiation with neutrons, and the subsequent measurement of the radiation (often gamma rays) emitted during the decay of these radioactive nuclei ([Fig. 2](#)). In principle, over 70 elements can be detected in amounts as small as micrograms to nanograms, or even less, depending on the physical characteristics of the element and other elements present in the object analysed ([Parry, 1991](#); [Ehmann and Vance, 1991](#); [Greenberg et al., 2011](#); [Grdeń, 2020](#)).

NAA is the second most common application, and the most common analytical technique at RRs ([Table 1](#)), from subcritical and critical assemblies to RRs with power ratings up to 200 MW ([International Atomic Energy Agency, n.d.-a](#)). RRs with power above 10 kW have thermal neutron fluxes already sufficient for most of the applications of NAA, and NAA is mostly done at RRs with power rating between 10 kW and 5 MW. The higher fluxes at these reactors lead to lower detection limits.

Most samples are multi-elemental, leading to a mixture of radioactive nuclei with short, medium and long half-lives after irradiation. The energy of the emitted gamma ray is characteristic of the emitter and is used to identify the element present. Some gamma rays of radionuclides of different elements have close-by energies, and a high intensity from one radionuclide can mask the signal from another. This may be resolved by taking advantage of the differences in half-lives; the initially masked signals

Fig. 2 NAA Technician loading a sample in the automated short-lived cyclic system at the University of Texas research reactor. Courtesy of the University of Texas Nuclear Engineering Teaching Lab, United States of America.

may become visible once the interfering activity has decayed away. In instrumental NAA (INAA), successive measurements are therefore taken after different decay times (for instance immediately after irradiation, 3–5 days later, and 2–3 weeks later). The combined analysis of these measurements may result in information on 50–60 elements. Less commonly, chemical separation of the irradiated sample leads to split it into fractions with only a few non-interfering radionuclides in each, leading to better detection limits. This destructive technique is called radiochemical NAA (RNAA) (Heydorn, 2000).

One common variant of INAA is epithermal NAA (ENAA), where only epithermal (and fast) neutrons are used by shielding the sample with a thermal neutron absorber such as cadmium or boron (Alfassi, 1985). This can increase the sensitivity to elements with higher epithermal than thermal activation rate, or in the presence of interfering radionuclides with different epithermal and thermal activation rates. NAA with fast neutrons is rarely done at RRs as it requires more complex absorbers for both the thermal and the epithermal neutrons; it is more common with accelerator based neutron sources, D-D or D-T generators and even with isotopic sources.

Delayed neutron counting (DNC) is a form of NAA to measure thorium and uranium by measurement of neutrons emitted by fission products or their daughters.

NAA requires appropriate irradiation positions with a well characterizable neutron spectrum. Short irradiations are usually done with a pneumatic (less commonly, hydraulic) sample transfer system, which for NAA and DNC should have transfer times around 1–2 s. Long irradiations can be done also with such systems or by manual insertion and removal of samples from the irradiation position. For ENAA, irradiation positions surrounded by thermal neutron shielding (e.g., a 1 mm thick cadmium sheet) are common. Counting of the induced activity is done with a gamma ray spectrometer, usually employing a high resolution germanium semiconductor detector. Compton suppression systems can significantly improve the detection limits for some radionuclides, but increase the complexity and cost of the system. Automation of the NAA workflow and use of multiple counting stations can lead to capacities up to 1000 samples per month (International Atomic Energy Agency, 2017).

NAA is complementary to other analytical techniques for determination of elemental compositions, such as inductively coupled plasma mass spectrometry (ICP-MS), X-ray fluorescence (XRF), particle-induced X-ray emission (PIXE), and others. Strengths of NAA include (Grdeń, 2020):

- Real total bulk analysis for sample masses from micrograms to several kilograms (International Atomic Energy Agency, 2018) of objects of various dimensions and shapes (Grdeń, 2020);
- No dissolution of sample (except in RNAA), therefore preservation of sample and no losses of measurand;

- Accuracy not affected by the chemical state and physical form of the elements;
- Matrix independence; no need for matrix matched calibrators;
- Many adjustable experimental parameters for optimization to suit specific needs;
- High degree of isotopic and elemental specificity;
- High degree of accuracy; all sources of uncertainty can be quantified (Greenberg et al., 2011);
- Neutron activation of elements such as H, C, N, O, Si do not result in measurable induced activity. Many sample matrices become “transparent” for the signals from the trace elements of interest;
- RNAA is done with direct measurement of the chemical yield of the separation (by adding a known amount of non-radioactive carrier prior to the chemical separation), leading to highly accurate measurements;
- The measurement instrumentation is relatively inexpensive, robust and with very little maintenance requirements.

NAA is particularly well suited to application niches with solid samples that are either

- Difficult to dissolve completely;
- Easy to contaminate during preparation of the test portion;
- Unique and should keep their integrity; or
- For which other techniques are lacking matrix matched calibrators.

Some examples are plastics, soil, rock, bulk analysis of coal, ores and minerals, plant material, glass, catalysts, difficult elements such as halogens, arsenic, antimony and mercury, high purity compounds of carbon fiber, silicon and composites, air particulate matter, human or animal tissue, forensics, archaeological and cultural artefacts, and entire or very large test portions.

Prompt gamma analysis

In prompt gamma analysis (PGA) the gamma radiation emitted in the neutron capture (n,γ) reaction is detected (Grdeń, 2020; Molnár, 2004; Lindstrom et al., 2017). The terms prompt gamma NAA (PGNAA) or prompt gamma activation analysis (PGAA) are also commonly used even if the radiation emitted by the activated reaction product does not play a role.

Like NAA, PGA is a non-destructive isotope-specific analytical technique for the determination of presence of elements and of their amount in samples weighting from a few micrograms to several kilograms. The IAEA database for PGA has data for more than 80 elements (International Atomic Energy Agency, 2003). In a high flux RR, up to 40–50 elements may be measured with detection limits ranging typically from 0.01 μg to 1 mg (Paul et al., 2015). In practice, PGA is most useful for trace elements that cannot be easily (or at all) measured with NAA, such as H (Couet et al., 2012), B (Paul, 2005), C, N, Si, P, S, Cd and Gd. Some of these elements can be determined with other analytical techniques, but PGA has the same advantages that were listed for NAA above.

While in NAA the samples are first irradiated and then the resulting activity is counted after a certain decay time, in PGA the counting takes place while irradiating the sample. Hence PGA is performed in neutron beam positions, requiring adequate shielding, and only one sample can be measured at a time. Irradiation times of several hours are often required to attain the desired sensitivity, particularly for multielemental analysis, which leads to a much lower throughput of samples than can be achieved with NAA.

Activation rates are in general higher for cold neutrons. The most sensitive set-ups therefore use cold neutrons and suppress fast and epithermal neutrons and background gamma rays by using a curved neutron guide.

PGA with isotopic sources such as ^{252}Cf or portable DD/DT generators are widely used in the coal, power, cement, iron ore and steel industries for real time analysis of bulk materials, as well as for detection and identification of explosives, land mines and unexploded ordnance (Martin et al., 2000).

Radioisotope production

Radioisotopes play a key role in many areas of human activity with very high economic and social impact, including medicine, industry, agriculture and R&D. Most radioisotopes used in those fields are produced in RRs or accelerators (usually cyclotrons), with production in nuclear power plants being limited to a few important RIs with high demand, such as ^{60}Co and ^{137}Cs .

Research reactor radioisotopes

Some radioisotopes produced in RRs are shown in Table 4, together with the applications for which they are used (International Atomic Energy Agency, 2003). The list is by no means exhaustive, and many other RIs can be produced in RRs. Medical applications include diagnostic—imaging with radiolabeled molecules, therapy—using the radiation emitted by the RI to destroy affected cells, and palliation, i.e. pain-reducing therapeutic relief. Radiotracers are also used in a wide array of industrial applications including process control, chemistry and agriculture. Strong neutron emitters such as ^{252}Cf are used in industrial PGA, as start-up source in nuclear reactors and in well logging in the oil industry. In all these applications, including medicine and industry, there are opportunities for R&D, including radiotracer studies in scientific research.

Table 4 Some radioisotopes produced in RRs as a function of the thermal neutron flux. For each flux range, the radioisotopes indicated are additional to those shown in lower flux ranges. The operation cycle also determines the RIs that can be produced in a given RR.

Thermal neutron flux ($\text{cm}^{-2} \cdot \text{s}^{-1}$)	Some radioisotopes produced	Typical application
$< 10^{12}$	^{24}Na	Radiotracer in industrial and medical applications
	^{38}Cl	Radiotracer in industrial applications (organic chemistry)
	^{41}Ar	Radiotracer in industrial applications
	^{56}Mn	Radiotracer in industrial applications
	^{64}Cu	Therapy and diagnostic: cancer imaging and theranostic agent
$10^{12} - 10^{14}$	^{198}Au	Radiotracer in industrial applications Therapy: different cancers
	^{32}P	Radiotracer in industrial applications (hydrology) Therapy: radiosynoviorthesis, ^a blood cancer
	^{35}S	Radiotracer in industrial applications (agriculture)
	^{51}Cr	Radiotracer in biological and medical research Diagnostic: hematology
	$^{60}\text{Co}^b$	Radiotracer in industrial applications Industrial: sterilization; process control; materials science
	^{82}Br	Industrial: chemistry applications
	^{90}Y	Palliation: metastatic bone pain Therapy: neuroendocrine cancers, hepatocellular carcinoma, lymphoma
	^{99}Mo	Diagnostic: $^{99\text{m}}\text{Tc}$ (from ^{99}Mo) for oncology and cardiology
	^{125}I	Therapy: brachytherapy and prostate cancer
	^{131}I	Therapy: thyroid cancer, hyperthyroidism, neuroblastoma
	^{133}Xe	Diagnostic: lung function
	^{153}Sm	Palliation: metastatic bone pain
	^{165}Dy	Therapy: radiosynoviorthesis ^a
	^{169}Er	Therapy: radiosynoviorthesis ^a
	^{169}Yb	Therapy: brachytherapy
	^{177}Lu	Therapy: solid tumors
	^{186}Re	Therapy: cardiology Palliation: metastatic bone pain
	^{192}Ir	Therapy: brachytherapy Industrial: radiography
	^{203}Hg	Industrial: chemistry applications
$> 10^{14}$	^{75}Se	Palliation: metastatic bone pain
	^{89}Sr	Palliation: metastatic bone pain
	^{103}Pd	Therapy: brachytherapy for prostate and brain cancers
	$^{117\text{m}}\text{Sn}$	Therapy: radiosynoviorthesis ^a Palliation: metastatic bone pain
	^{188}W	Therapy: ^{188}Re (from ^{188}W) cardiology
	^{252}Cf	Industrial: strong neutron emitter

^aRadiosynoviorthesis is a procedure for the local treatment of chronic inflammatory joint diseases.

^bMost high specific activity ^{60}Co is produced at NPPs.

In RRs, RIs are produced by neutron induced reactions, capture or fission on a target material, leading either to activation of the target material or to fission. Fission has the advantages that many different RIs can be obtained and that higher specific activities can be reached with appropriate processing. In capture the common (n, γ) reaction is often used; in that case, chemical separation of the daughter from the target is often not possible, leading to lower specific activities. Whatever the method, three parameters are normally important to consider for the RIs produced, needing to be within the limits prescribed by the end user: the specific activity; the chemical purity (contamination by stable isotopes); and the radiochemical purity (contamination by other RIs).

The neutron flux determines which radioisotopes can be produced with given desired specific activities in a given RR. Commercial production of RIs usually requires the availability of high neutron fluxes. Medium neutron fluxes can be sufficient for many applications, even low scale commercial production or for local supply. Low flux RRs are also often used to produce RIs, for R&D or for demonstration (often within E&T programs) purposes. The operation cycle plays an essential role: to reach high specific activities of long-lived RIs continuous operation during extended periods is needed. For instance, commercial producers of ^{99}Mo typically operate in cycles of 3–4 weeks, but other RIs may require longer periods of several months. Operation in daily shifts limits the capability of an RR to short lived RIs only, which may be appropriate for low power RRs. Sequential neutron capture, needed to produce some RIs such as $^{186}\text{W}(n, \gamma)^{187}\text{W}(n, \gamma)^{188}\text{W}(\beta^-)^{188}\text{Re}$, is only efficient in very high flux reactors.

RI production involves a series of interrelated steps that go much beyond actual irradiation in the RR: fabrication of appropriate targets and their encapsulation; their irradiation; transportation of the irradiated targets to host cells and radiochemical processing

facilities; processing or encapsulation into sealed sources; quality control; and transportation to end users. Processing of the irradiated targets can be a complex and costly activity, requiring hot cell facilities and associated equipment. Particularly in large-scale commercial production, it is often done elsewhere by a specialized company. In such cases the reactor operator only needs the capacity to irradiate and handle the targets, including their packaging and transport, according to national (and international) regulations, respecting radiation protection requirements and ensuring safety at all times. Commercial medical RI production requires the establishment of a QA/QC system and respecting good manufacturing practices (GMP) requirements (World Health Organization, 2014).

Molybdenum-99 production

Radiopharmaceuticals are radioisotopes bound to biological molecules able to target specific organs, tissues or cells within the human body.

On a global scale, there are some 50 million nuclear medicine procedures with RIs per year (World Nuclear Association, 2020). Developed countries account for about one quarter of the world's population and over 80% of the demand of RIs. Correspondingly, estimated market growth rates were 0.5% for mature markets and 5% for developing markets (at the end of 2018 (Nuclear Energy Agency, 2019)), and production of RIs was one of the major motivations behind a majority of projects for new RRs in developing countries, in spite of the fact that entry of newcomers to the market is difficult due to the large investment needed, regulatory hurdles and commercial factors.

Diagnosis accounts for 90% of medical procedures involving RIs, and Technetium-99 (^{99m}Tc) alone is used in about 85% of diagnosis scans with radioisotopes. The short (6 h) half-life of ^{99m}Tc means it cannot be produced, processed and delivered in time to the end users. Instead, ^{99}Mo , which decays to ^{99m}Tc with a half-life of 2.75 days, is used as the source in $^{99}\text{Mo}/^{99m}\text{Tc}$ generators. The widespread use of ^{99}Mo is due to its ease of production and handling, high specific activity, reliable product quality, and the fact that ^{99m}Tc can be attached to several specific molecules, forming diverse radiopharmaceuticals for the diagnosis of many diseases, including certain types of cancers (Fig. 3).

Large scale production of ^{99}Mo , which decays to ^{99m}Tc with a half-life of 2.75 days, is made in a small number of RRs by fission of ^{235}U . Historically, highly enriched (HEU) targets were used, but low enriched uranium targets (enriched in ^{235}U by less than 20%) are available and most major producers either are already using LEU or intend to convert from HEU to LEU targets (International Atomic Energy Agency, 2013b; Nuclear and Radiation Studies Board et al., 2017). Low scale production can also be made from activation of natural Mo or enriched in ^{98}Mo targets (International Atomic Energy Agency, 2015a).

There are also only a few major processing facilities, and a global supply chain $^{99}\text{Mo}/^{99m}\text{Tc}$ generators is established taking into account the irradiation and processing capacities, the complex logistics established, as well as planned RR operation and outage schedules (e.g. due to planned maintenance or refueling). Nevertheless, unexpected simultaneous shutdowns of some of these RRs led to a global ^{99m}Tc shortage in 2009–10, and in 2019 the supply chain was more stable but still frail (Nuclear Energy Agency, 2019). The 2020 covid-19 pandemic led to some difficulties in transport and distribution of radioisotopes worldwide. At the same time, new concepts are being developed, including direct target irradiations at particle accelerators (International Atomic Energy Agency, 2017b) or using accelerator driven homogeneous aqueous solution subcritical assemblies (International Atomic Energy Agency, 2008a).

Geochronology and thermochronology

Research reactors can be used as tools for radiometric dating in geochronology and in thermochronology, which study, respectively, the age and the thermal evolution of rocks, minerals, fossils and sediments.

Fig. 3 Left: Molybdenum plate in holder. Centre and right: radiopharmaceuticals ready to be shipped. Courtesy of NECSA, South Africa.

Ar geochronology

Potassium is the eighth most abundant element in the Earth's crust, with around 2 wt%, and it is a major or minor component in many minerals. It has three natural isotopes including the radioactive ^{40}K , with 0.012% abundance and a 1248 million years half-life. It decays to the stable isotopes ^{40}Ca (89.28%) and ^{40}Ar (10.72%). By measuring the amount of ^{40}K and of radiogenic ^{40}Ar in a mineral, their age can be determined. ^{40}Ca is not useful because Ca is a common element in minerals.

K–Ar dating is used in geological problems since 1950. It relies on absolute determination of the abundances of both isotopes (requiring separate aliquots) and on several assumptions that cannot always be reliably verified. $^{40}\text{Ar}/^{39}\text{Ar}$ dating, developed in the 1960s, is based on a relative measurement on the same aliquot and is much more accurate. It also requires much smaller masses, on the sub milligram range, and is capable of determining the age of micrometer sized grains, from volcanic rocks as young as two millennia to rocks from the moon or as old as Earth itself.

$^{40}\text{Ar}/^{39}\text{Ar}$ dating is based on irradiating the sample with fast neutrons. The amount of potassium is determined using the $^{39}\text{K}(\text{n}, \text{p})^{39}\text{Ar}$ reaction, which has a threshold of 1.2 MeV. The ratio of ^{40}Ar to ^{39}Ar is determined with mass spectrometry (with outgassing due to heating of the sample), and is used to calculate the date. Interfering reactions on different elements and atmospheric ^{40}Ar not of radiogenic origin can be accounted for.

Minerals formed at high temperatures only started to retain the ^{40}Ar after a certain period of cooling. The age determined by $^{40}\text{Ar}/^{39}\text{Ar}$ corresponds to the time where diffusion loss stopped. Thermochronology takes advantage of this to determine the thermal history of the samples by stepwise heating them while performing mass spectrometry (McDougall and Harrison, 1999). Laser heating for spot analysis leads to age mapping of samples with micrometer spatial resolution (Kelley, 2002).

Research reactors are typically only involved in the irradiations and the analysis is often done off-site in specialized laboratories. The main requirement is a sufficiently high fast neutron flux. Typically a 1 MW power is needed for relatively “young” samples and 10 MW for “older” samples.

Fission track geochronology

Fission track dating is a relatively simple method for determining the age and thermal history of uranium-rich minerals such as apatite, zircon, titanite and natural glasses, with ages starting at around 100,000 years.

When ^{238}U undergoes spontaneous fission, the fission products create tracks in the material. By measuring the fission track density and the amount of uranium in the sample, its age can be determined. Irradiation with thermal neutrons leads to fission of ^{235}U , which creates more tracks. Counting the track density before and after irradiation, the ^{235}U content is also determined, providing the total uranium content through its known natural abundance (Tagami and O'Sullivan, 2005).

The fission tracks are revealed by chemical etching and counted visually. Since ^{238}U and ^{232}Th undergo fission when irradiated with fast neutrons, a highly thermalized spectrum is needed. In the thermal column of a medium power RR with fairly low flux, long irradiation times may be needed, up to several days. In a heavy water moderated RR the thermal neutron flux can be much higher leading to much lower irradiation times.

The fission tracks are progressively shortened and disappear when the rock is heated, depending on the temperature and time. Track fading and track length therefore give indication on the thermal history of the sample, and fission track thermochronology, usually done in off-site in specialized facilities, has been applied to problems such as tectonics, petrology, stratigraphy, hydrocarbon exploration and geomorphology (Malusa and Fitzgerald, 2019) (Fig. 4).

Fig. 4 Inspection of fission tracks after irradiation at the IEA-R1 research reactor of IPEN. Courtesy of IPEN/UNICAMP, Brazil.

Transmutation effects

Neutron and gamma radiation can induce changes in the properties of materials, opening fields of application of research reactors not only in research, but mainly in the provision of commercial products and services. Relatively high and uniform fluences are often required to enact the desired changes, and this activity usually requires a high or medium power RR with adequate irradiation positions.

Silicon transmutation doping

Neutron transmutation doping (NTD) is a method to introduce dopants in intrinsic or extrinsic semiconductors ([International Atomic Energy Agency, 2012](#)). It is widely used to dope silicon with phosphorus via the reaction $^{30}\text{Si}(n,\gamma)^{31}\text{Si}$ with subsequent beta decay to ^{31}P ($T_{1/2} = 2.62$ h). Irradiated silicon is used in high quality devices for high power applications such as thyristors and high-voltage power rectifiers, due to the very high accuracy and uniformity of the dopant concentration that can be achieved. Other semiconductors such as Ge ([International Atomic Energy Agency, 2012](#); [Malar et al., 2014](#)) can also be doped with NTD, but large scale commercial activity is concentrated in irradiation of silicon.

NTD requires specially designed irradiation positions, which should have fast neutron and gamma fluxes as low as possible, since they cause electrically charged defects in the silicon lattice and heating, respectively. Uniformity of irradiation at the ingot is achieved by rotating the ingot (and in some facilities, inverting it at half the irradiation time), and with flux screens designed taking into account the flux's axial profile to create a flat flux profile at the ingot. Cooling must be provided. The irradiation positions must be sufficiently large to accommodate ingots with 4, 5, 6 or 8 in. diameter, with demand currently concentrated on 6 and 8 in. ingots.

The main producers of NTD silicon have power ratings of 20 MW or more, but several RRs with power rating from 3 MW also have or are planning activity in the area ([International Atomic Energy Agency, 2012](#)) ([Fig. 5](#)).

Gemstone coloring

The color of gemstones can be changed by irradiation with high energy neutrons, electrons, gamma radiation or a combination of these, creating intrinsic color centers in the gemstones and leading to an increased market value. Neutron irradiation is most often applied to colorless topaz, that acquire a blue color with intensity that increases nearly linearly with the fluence ([Leal et al., 2007](#)). Typical fast neutron fluences for commercial purposes range from 10^{17} to 10^{18} cm^{-2} . The thermal neutron fluence must be minimized.

The resulting gemstones are activated, and decay times from several months to a few years are needed before they are introduced in the market, depending on the impurities in the original material ([Zhang et al., 2011](#)). The practice is forbidden in some countries and regulated in others, such as in the United States by the US Nuclear Regulatory Commission.

Gamma irradiation

Irradiated fuel assemblies can be utilized as source for a gamma irradiation facility, usually located in the service pool. The achievable dose rates can range from around 2 to 200 Gy/h, depending on the reactor power and fuel history. Applications range from irradiation of plants and seeds to the study of radiation effects on materials.

Fig. 5 Left: a silicon array being loaded into an irradiation facility of the OPAL research reactor. Right: irradiated silicon ingots. Courtesy of ANSTO, Australia.

Transmutation of minor actinides

Long-lived minor actinides are a component of irradiated nuclear fuel with significant radiotoxicity. Subcritical accelerator driven systems have been designed for transmutation of the minor actinides into shorter lived isotopes with reduced radiotoxicity and thermal output (Abderrahim et al., 2000). Research reactors can also be utilized to provide needed experimental data (Guidez et al., 2004).

Neutron imaging

Neutron imaging exploits the penetration of neutrons in objects to study their internal structure (International Atomic Energy Agency, 2008b, 2015b). Neutrons interact mainly with the nuclei and with magnetic fields. They are strongly attenuated by light elements such as hydrogen (and by a few specific heavier elements such as cadmium), contrarily to X-rays, which interact with the electron clouds and are more attenuated by heavier elements. Therefore, neutron imaging is often complementary to the corresponding X-ray technique. During the last two decades, most of film-based detection has been replaced by digital imaging, which led to the widespread adoption of 3D computed digital tomography, where the inner structure of the object is reconstructed based on many 2D images taken at different angles (Schillinger et al., 1999).

With time-series or stroboscopic techniques with frame acquisition time from a fraction of a second down to 10 μ s, dynamic processes can be followed (Tremsin et al., 2010; Tötzke et al., 2017, 2019). Advanced imaging techniques beyond imaging by absorption were developed, opening up new possibilities in NDT (Lehmann et al., 2017). These techniques take advantage of the availability of cold neutron beams, monochromators and beam conditioning and detection systems such as grating interferometers and neutron polarizers, to visualize the crystalline structure, crystal orientation, strain, magnetic domain walls and magnetic fields. Spatial resolutions down to 10 μ m have been achieved in some systems. Fields of view commonly range from 10 to 40 cm diameter or side length.

Neutron imaging, in its diverse variants, finds preferential fields of application in NDT, in particular for visualization of the inner structure of intact objects, which are either unique, precious or costly to replace, when operando analysis of dynamic processes is needed, and when it can provide unique information not available with other techniques. Applications include, for instance: 3D hydrogen distribution in fuel cells and other technological devices; efficiency and performance of engines and batteries; quality control of turbine blades and other mechanical components in the car, aviation and building industries; NDT of nuclear fuel and other nuclear materials; provenance and technology of objects in cultural heritage; and diverse applications in life sciences, geology, soil physics and materials research (Fig. 6).

A number of medium and low flux RRs have some neutron imaging capabilities, often using thermal neutrons. Important niches of applications can be found in such cases, including 2D radiography of industrial components or cultural heritage. At low fluxes on

Fig. 6 Real time high speed neutron imaging of water uptake in roots of lupine (a) Radiographic projection image, (b) segmented root system; (c–e) water ascent. Courtesy of University of Potsdam and Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany.

the sample, long image acquisition times may impede 3D tomography. Advanced neutron imaging techniques are normally found at high flux RRs and spallation neutron sources.

Materials research

Innovative technological applications depend on the development of new materials with specifically designed and optimized properties, for which understanding the complex interplay between their properties and structure plays a crucial role. Materials research thus depends on appropriate characterization techniques capable of providing insights on matter from the atomic to large scale structure and ordering, 2D and 3D nanosystems, and on atomic and molecular dynamics and electric and magnetic structure.

Neutron scattering

Neutrons have wavelengths similar to interatomic spacing, kinetic energies similar to that of atoms and a magnetic dipole, which makes them ideal probes of atomic structure, atomic dynamics and magnetism, respectively (Guidez et al., 2004; International Atomic Energy Agency, 2006a,b; Furrer et al., 2009; Scattering et al., 2012). They have very large penetration depths (in the absence of strong neutron absorbers), which means they can probe bulk materials, and they are isotope-specific. Their energy and polarization can be controlled. These properties are of particular importance for neutron scattering, because they can be used in diverse variations of the technique, using specialized instruments, to probe different aspects of matter and length scales. Similarly to neutron imaging, neutron scattering is performed optimally at high flux RR or spallation neutron sources, and is often complementary to scattering techniques that use X-rays, light or electrons as probe. In soft matter studies, isotopic substitution by exchange or selective labelling of part of the system by deuteration is a key technique, taking advantage of the strong contrast in neutron scattering between hydrogen and deuterium.

The study of structural and magnetic properties at the atomic scale typically uses wide angle diffraction. The main techniques used are powder diffraction and single crystal diffraction, often using thermal neutrons, but hot or cold neutron sources are needed for some applications. Applications are, among others, phase, texture and structure determination in materials such as metals and alloys, inorganic compounds and ceramics and liquid and amorphous materials; location of light elements such as hydrogen in complex materials; stress analysis in mechanical components; determination of magnetic and spin structures in e.g. high temperature superconductors and molecular magnets.

Large scale structures, on lengths from the nm to the near- μm range, are typically studied with small angle neutron scattering (SANS) and neutron reflectometry, usually with cold neutrons. SANS is the most widely used neutron technique for structure determination, and applications include the study of molecular structure of macromolecules such as polymers, proteins and other biological molecules; cell membranes, surfactants and other surface systems; micelles, dendrimers, colloidal particles and microemulsions; and magnetic and spin systems such as magnetic nanoparticles, nanolayers, clusters, vortices and superconductors. Ultra-small angle neutron scattering (U-SANS) extends the scale range to $10\ \mu\text{m}$ (at the cost of loss of 2D information) and is applied to study micro-structural properties of polymer blends, structural steels, natural composites, complex fluids and colloidal crystals and alloys and other systems with complex morphology. Neutron reflectometry is used to characterize the thickness, structure, density, roughness and magnetic properties of thin films, multilayers and interfaces at the nanometer scale and to depths up to 100 nm. This finds applications in many fields, including the study of magnetic nanosystems; surfactants, complex fluids and liquid-liquid interfaces; kinetic studies of layer and interface evolution, polymer diffusion, protein unfolding and others; self-assembly and self-organization.

Atomic and molecular dynamic processes are studied with inelastic and quasi-elastic scattering, where the neutrons exchange kinetic energy with the lattice nuclei, thus creating or annihilating an excitation probing collective excitations of the lattice (phonons) and of the electron spin structure (magnons), as well as atomic diffusion. Both direction and energy of the scattered neutrons must be detected, and several techniques have been developed, such as triple axis spectrometry, time-of-flight (TOF) spectrometry, backscattering spectrometry and neutron spin echo. Thermal, cold or hot neutrons may be used depending on the system and properties under study. In spite of the complexity of some of the techniques, inelastic and quasi-elastic scattering have found application in many areas, including, for instance, determination of interatomic forces and magnetic coupling; behavior of quantum magnets and superconductors; dynamics of soft and biological matter; local and long range diffusion, including hydrogen in batteries and fast ion conductors; phase transitions (Fig. 7).

Neutron depth profiling

The elemental and isotopic composition of materials often determines their properties. NAA and PGAA provide the quantity of matter in samples, but are not sensitive to the change with depth of elemental concentrations, which is essential in the layered systems that make up nearly all modern technological materials. There are many depth profiling techniques based on ions, electrons and photons as probing particles. In many cases, successive sputtering of surface layers is employed in conjunction with a surface probing technique.

Neutron depth profiling provides quantitative depth profiles of some light elements such as He, Li, Be, B and others, independently of the sample matrix and non-destructively. Thermal neutrons lead to a nuclear reaction with emission of charged particles

Fig. 7 A Triple Axis Spectrometer installed at BATAN's RSG-GAS research reactor. Courtesy of BATAN, Indonesia.

(typically a proton, tritium, alpha, or other light nuclei) with energies ranging from a few tens or hundreds of keV to several MeV. These particles lose energy as they traverse the sample, and so emerge and are detected with reduced energy. The yield as function of energy can be easily translated into the concentration as function of depth.

Neutron depth profiling has been extensively used for real-time in-situ quantification of the changing lithium distribution in rechargeable lithium-ion batteries during charging and discharging. The Li depth profile can be determined over a range of 20 μm or more using the reaction ${}^6\text{Li}(n,\alpha){}^3\text{H}$, with acquisition times of a few minutes, which is sufficient for operando analysis (Liu et al., 2014), and 3D reconstructions of high and low regions of Li concentration are also possible (He et al., 2015).

Positron sources

Positrons are used as probes in the positron annihilation lifetime spectroscopy (PALS) which is a non-destructive technique that probes defects, voids, and open-volume defects in materials from the sub-nm scale to large vacancy clusters, with application in solid state physics and materials science, including semiconductors, metals and alloys, polymers and biological systems (Siegel, 1980). The depth distribution of the defects can be determined and, employing a positron microbeam, a sub-micrometer resolution lateral distribution can also be obtained. Doppler-broadening spectroscopy and angular correlation of annihilation radiation take advantage of conservation of momentum during the annihilation process to provide information on electron momentum distributions and are sensitive to the chemical environment of the annihilation site. Intense positron beams are used in atomic physics and nuclear astrophysics.

There are several paths to produce positrons, from β^+ isotopic sources, accelerator based sources, and RRs. In RRs, positrons can be produced by neutron activation of suitable targets such as copper, or by high energy gamma rays (from fissions in the core, or from neutron capture e.g. by cadmium) that are then absorbed by a high atomic number target such as platinum or tungsten (Hugenschmidt, 2017). The positrons produced are moderated to the desired energy. RRs with 100 kW can create around 10^7 moderated positrons per second. Well-designed facilities at high power RRs can reach two orders of magnitude higher values.

Neutron therapy

Neutron therapy uses neutron capture reactions such as ${}^{10}\text{B}(n,\alpha){}^7\text{Li}$, ${}^6\text{Li}(n,\alpha){}^3\text{H}$ or ${}^{157}\text{Gd}(n,\gamma){}^{158}\text{Gd}$. The reaction products (or, in the case of ${}^{157}\text{Gd}$, gamma rays and electrons) have MeV energies and a range in tissue comparable to cell dimensions, resulting in high Linear Energy Transfer (LET). The increased biological effects will be localized at the tumor cells if the ${}^{10}\text{B}$ is selectively concentrated there, with minimized damage to healthy tissue.

Distance to hospitals and public acceptance of nuclear reactors in a context of health care have hindered widespread use of RR based neutron therapy, with not more than a few thousand patients treated, many in the context of clinical trials. Strong side effects and inconclusive or insufficient clinical results, together with the development of new techniques including low-LET and high precision dose delivery methods also led to a reduction of the number of available facilities and of patients treated (Wagner et al., 2012). Current efforts are directed towards accelerator based neutron sources adequate for use in a hospital context.

Boron neutron capture therapy

Boron neutron capture therapy (BNCT) uses a thermal neutron beam for treatment of shallow tumors, sometimes combined with epithermal neutrons to extend the effect up to 10 cm depth (International Atomic Energy Agency, 2001b). Nearly 1400 patients were treated by 2020 in over 20 RRs, mainly in clinical studies in Japan, Finland, the United States, China (mainland and Taiwan), Netherlands, Sweden, Argentina, Czech Republic and Italy, with basic research done in further countries. Most of these facilities are no longer operating. Variable results have been obtained in treatment and palliation of a number of different cancers, and the efficiency of BNCT is still unproven. Research focus on malignant melanomas and brain tumors. Development of appropriate radio-pharmaceuticals, uptake and distribution of boron, treatment planning and treatment schedules, mixed neutron and gamma fields and tolerable doses and dosimetry are still challenging areas of research (Fig. 8).

Fast neutron therapy

Around 30,000 patients have been treated with fast neutron therapy (FNT) with accelerator based and isotopic neutron sources. Less than 2000 were treated in three RRs in Germany and the Russian Federation, of which one continues this activity (Specht et al., 2015), together with a number of accelerator based neutron sources. There is some clinical evidence that the addition of FNT to gamma treatment leads to superior results in some specific situations. FNT has been used in treatment and palliation of different tumors including salivary gland tumors, recurrent malignant melanoma and metastatic skin lesions.

Materials testing

Rrs can use the neutron and gamma radiation for testing and calibration of materials and instruments (Giot et al., 2017; International Atomic Energy Agency, 2007b, 2011). Even low power RRs can perform instrument testing and calibration, while testing of nuclear materials such as nuclear fuel and reactor structural components is normally done in high power RRs operated by experienced organizations such as national laboratories or research centers.

Neutron and gamma detectors and instruments need to be calibrated and tested to ensure correct operation. This can be made at nearly any RR, independently of power. Some of these instruments are self-powered neutron detectors (SPND), fission chambers,

nuclear heating instrumentation and radiological protection instruments (International Atomic Energy Agency, 2017c). A RR where calibration of instruments is an important activity may require accreditation.

Testing of materials typically uses fast neutrons with fluence in the range from 10^{17} to 10^{21} cm^{-2} and higher. The purpose is to relate the neutron fluence to the ageing and degradation of the material's properties. Typical applications include study of embrittlement, stress corrosion and ageing of reactor pressure vessels, other nuclear reactor materials, fusion reactor materials, and materials used in spallation neutron sources. Study of the failure of electronic components under irradiation is also common, including those for space applications.

Testing of nuclear fuels is usually made in instrumented closed loops, where environment parameters such as temperature, pressure and coolant flow and chemistry can be controlled to resemble the expected operating conditions of the fuel. The neutron spectrum should also be matched to real operating conditions. Two main types of experiments are performed, namely to study burnup under steady state conditions, and to study the behavior of fuel and cladding under transient conditions (Fig. 9).

Other applications

R Rs have been widely used in other areas, namely determination of nuclear data such as cross sections, branching ratios, decay constants, etc. which are essential for nearly all fields of application, and provision of benchmarking data for validation and verification of codes for calculation of e.g. neutronics, thermohydraulics and activation of materials. A number of R Rs were built to model proposed new concepts of power reactor or accelerator driven system, e.g. to validate purpose-developed codes, to determine parameters such as flux and power, and assess safety margins. R Rs are also used for shielding experiments, namely to test new shielding designs and materials. Some R Rs have been used to generate heat and electricity, or to test design concepts for new generation NPPs.

Introduction

This survey of Idaho's experimental, test, and demonstration reactor programs describes their history from the perspective of why they came to be, and what impact they had, or failed to have. Many of the technical details of the reactor technologies, and in a few cases the Idaho reactors themselves, are described elsewhere in this encyclopedia as well as in readily available reference materials. The U.S. Department of Energy (DOE) published the official compendium of Idaho's fifty-year, fifty-plus reactor history ([Stacy, 2000](#)), where more details can be found.

Idaho National Laboratory

INL is the acronym for Idaho National Laboratory. Officially created in 2005, for simplicity this history of the site since 1949 has been pulled together under the INL moniker, although the spirit of the story resides within the original designation—the National Reactor Testing Station. Many details of research-sponsoring agencies, site contractors, and key personalities are skipped in this short account of Idaho's role the development of nuclear energy.

Atomic Energy Commission selects Idaho

By the time that the Atomic Energy Commission (AEC) took over from the Manhattan Project in 1947, some of the nation's brightest people were considering power applications for nuclear energy. There were questions that could only be answered by experiments. Based on the lack of knowledge at the time, some of these experiments would pose unacceptable risks if sited near a metropolitan area. Aggressive reactor testing required a remote location. On March 1, 1949, the AEC announced that it had selected Idaho for the National Reactor Testing Station.

A proliferation of reactor technology concepts

With the capability to enrich uranium developed during the Manhattan Project, the U.S. could consider any conceptual reactor technology for commercial development. Technologies that did not require enriched uranium, such as heavy water moderated or graphite moderated reactors, were commercially pursued abroad. Exotic concepts for using solution fuels or very high temperature graphite reactors were investigated at other U.S. national laboratories. INL's principal focus was on light water cooled and liquid metal cooled concepts.

How many reactors were built at INL?

It depends. The commonly accepted number is 52. However, two of those reactors did not operate before the commercial concepts were eliminated. Another small reactor was simply borrowed from and returned to California. On the other hand, a critical facility was counted as a single reactor, whereas 63 unique benchmark and detailed engineering mockups reactors were built in the ZPR-3 facility and 21 were built in the large ZPPR facility ("reactors" ne.anl.gov). This survey highlights the reactors that had the biggest impact.

The right stuff

Among the oral histories of how Idaho was selected for the National Reactor Testing Station, there are three dominate threads: the local perspective of a successful political campaign; the dry official perspective of the AEC; and the one selected here—the perspective of the scientists and engineers responsible for the tests. Enrico Fermi's chief engineer for the world's first nuclear reactor CP-1, Argonne National Laboratory Director Walter Zinn recommended the Idaho site to the AEC. It had the right stuff for testing reactors under any conditions:

- Remote from any permanent development
- Access to cooling water
- Railroad infrastructure for heavy components
- Previously disturbed land
- Local support

Land and water

More than 61% of Idaho land is federally owned. Some 2250 km² of this land was carved out for reactor testing. The site is large enough to accommodate several widely separated operational hubs, while maintaining a nominal 50 km buffer zone from population centers. INL sits atop the northeast corner of the massive Snake River aquifer, which is capable of supplying cooling water for multiple medium-size power reactors.

Naval proving ground

Prior to its adoption for reactor testing, the site tested large naval guns that were refurbished in Pocatello, Idaho, transported by rail to a central location, and fired at buttes that jut from the desert plain. Several large conventional explosions contributed to testing safe storage of military ordinance. B-17 and B-24 bombers regularly blasted two small areas of the site prior to the end of World War II. There was little doubt that this rugged landscape could support a few test reactors.

No permanent settlement

There was no record of long-term human occupancy on the reactor test site. Subsequent cultural resource investigations revealed a rich history of hunting, gathering, crisscrossing travelers including Oregon Trail migrants and fur traders, Native American encampments, and failed homestead attempts ([DOE/ID, 2011](#)).

Strong community support

Supportive of the atomic dream like the rest of the country that in that era, the surrounding communities enthusiastically backed the test station and competed for the local AEC headquarters.

Bellwether achievements

Having spent 1948 drawing up plans, the AEC wasted no time in starting construction of key facilities in Idaho. By 1951, the first Idaho reactor, Experimental Breeder Reactor No. 1 (EBR-I), commenced operation. Without supercomputers, established supply chains, or modern construction methods, 17 reactors were operating on the site within 10 years. With national expertise in short supply, INL's first four reactors were designed at Argonne National Laboratory near Chicago, Illinois.

First nuclear electricity

Illuminating four light bulbs, EBR-I produced the first nuclear-generated electricity on December 20, 1951. It also demonstrated that breeding—the production of more fuel than is consumed—was attainable in a reactor with a high-energy neutron spectrum. Today EBR-I is an historical landmark open to visitors.

First materials testing reactor

Much larger and more complex than EBR-I, The Materials Test Reactor (MTR) began operating in 1952. Besides demonstrating a new high radiation flux technology, the MTR accelerated the screening of potential materials for use in promising reactor technologies. It was also the first building block of INL's sustaining research mission.

First large-scale application of nuclear energy

The Submarine Thermal Reactor (STR), also known as S1W, started up in 1953. This prototype reactor demonstrated the viability of the pressurized water reactor (PWR) technology to generate the mechanical power needed to turn a large propeller shaft. The U.S. Navy uses this technology in its nuclear ships. Two-thirds of the world's commercial nuclear powerplants employ PWR technology.

First town lighted by nuclear energy

The first boiling water reactor experiment (BORAX-I) also reached power in 1953. The five BORAX tests ran through 1958, demonstrating the viability of the boiling water reactor (BWR) concept. Today BWRs comprise 20% of the world's commercial nuclear powerplants. BORAX-III scored a notable first in 1955 when it supplied all the electricity to the town of Arco, Idaho, and several of the INL facilities.

Solid foundation for pursuit of commercial nuclear power

The early results from these four INL reactors put the AEC in a position to encourage private enterprise and international cooperation in future nuclear energy development ([American Nuclear Society, 1992](#)). President Eisenhower signed the Atomic Energy Act of 1954, the enabling legislation for cost sharing between government and industry in the Power Demonstration Reactor Program. Demonstration reactors began connecting the U.S. power grid in 1957.

Nuclear energy for the armed services

Drawing on the success of the Manhattan Project, all branches of the US military wanted to capitalize on nuclear energy to help achieve operational superiority. The Navy, the Air Force and the Army initiated projects to pursue their objectives. However, only the Navy had a mission for which there was no alternative to nuclear. The ambitions of the Army and the Air Force would be overtaken by competing technologies, but not before they made a significant footprint in Idaho.

Marine propulsion

The most successful reactor program with a footprint in Idaho is also the most difficult to document because of its military origin. The United States Navy, in conjunction with the AEC, initiated a project in 1949 to develop a nuclear-powered submarine under the leadership of Captain Hyman G. Rickover. ([U.S. DOE and U.S. Department of the Navy, 2014](#)). The fast-paced project bypassed established engineering development processes and set up simultaneous activities in New York, Pennsylvania, Connecticut, Illinois, and Idaho. Idaho's role was to construct and operate a prototype powerplant for the USS NAUTILUS, a submarine under construction in Groton, Connecticut. Westinghouse and the Bettis Atomic Power Laboratory were responsible for the engineering design, with core design support from Argonne National Laboratory. General Electric and the Knolls Atomic Power Laboratory were responsible for a competing sodium-cooled reactor design which was to power the USS SEAWOLF.

Naval prototype reactors

Nuclear power enabled the first true submarines by allowing ships to drive submerged at high speed for long periods without the need to resurface to obtain oxygen. Early submarines were essentially surface vessels that could submerge for short periods before resurfacing to run diesel engines to recharge batteries and oxygen supplies. Nuclear power also enhanced the capabilities of large aircraft carriers. Since 1955 the U.S. Navy has built more than 225 nuclear-powered ships, primarily submarines.

Submarine thermal reactor prototype

The Submarine Thermal Reactor, also known as S1W (submarine, first prototype, Westinghouse), was constructed at the new Naval Reactors Facility (NRF) on the INL site. STR was an exact prototype of the powerplant used in the USS NAUTILUS. Two precisely sized hull sections were used to house the reactor and the power equipment. The hulls were placed into a large water tank in order to replicate the radiation shielding conditions that would be necessary for the submarine. Following startup in early 1953, S1W simulated a 96-h submerged test run across the North Atlantic that eliminated any residual doubt about the feasibility of nuclear propulsion.

Aircraft carrier reactor prototype

Similar to the submarine program, the aircraft carrier first prototype A1W (aircraft carrier, first prototype, Westinghouse), simulated the essential features of a nuclear power system aboard a large aircraft carrier. Because of the size of these ships, multiple reactors were required. For the Idaho test, two reactors were built inside a large building at NRF. The novel feature was the use of both reactors to turn a single shaft. The arrangement simulated one engine room of the USS ENTERPRISE, which was to have a total of eight reactors. A1W achieved full power in 1959 and the ENTERPRISE went to sea in 1961.

Fifth generation submarine reactor prototype

NRF constructed a third prototype reactor in 1965. Known as the Natural Circulation Reactor, or S5G (submarine, fifth prototype, General Electric). S5G was built in a submarine hull section in a water tank. The hull could be rocked to simulate more realistic ocean conditions. The purpose of the new design was noise reduction by using natural circulation rather than pumps to circulate the cooling water for all but high-speed operation. This prototype supported the USS NARWAHL, which launched in 1967.

The Navy's continuing mission in Idaho

The naval reactor prototypes also found purpose in training navy personnel and testing new designs and equipment. The training mission phased out with the end of the cold war in the 1990s. Nevertheless, the Naval Reactors Program continued to have a major presence in Idaho as the primary experimenter in the materials testing reactors and supporting facilities. NRF continues to operate large nuclear facilities in support of the Navy's missions.

Dominance of the pressurized water reactor

Although the sodium cooled SEAWOLF performed satisfactorily, pressurized water technology was chosen for future US nuclear ships. These ships have compiled an outstanding performance and safety record. In the mid-1950s, the AEC began to transfer the technology to the private sector under its Power Demonstration Reactor Program. The AEC selected five companies for the construction of the first PWR plant, with the overall responsibility for the project assigned to Naval Reactors Branch, Division of Reactor Development ([American Nuclear Society, 1992](#)). The Shippingport, Pennsylvania plant began to deliver power to Duquesne Light Company customers in 1957. Operated by the utility, the plant reached its full power of 60 MW-electric on December 23, 1958. As of 2019, 297 PWRs were operating worldwide, with another 51 having shut down at the end of economic life ([Nuclear News, 2019](#)).

Failure to transfer

The enthusiasm for U.S. Navy nuclear ships did not transfer to merchant ships. Idaho conducted a brief program from 1962 to 1964 for a high temperature, air-cooled marine propulsion reactor. This low-power critical experiment, called 630-A, was discontinued when the nuclear power merchant ship program lost priority due to a projected lack of economic competitiveness.

Fantasy of flight

The US Air Force envisioned that a nuclear-powered aircraft could stay aloft without a need to refuel. The first priority would be to fly reconnaissance missions around Russia, each mission lasting multiple days. Take-off and landing would be accompanied by escorts prepared to deal with a crash. The Aircraft Nuclear Propulsion (ANP) program included activities across the US, with General Electric (GE) taking the design lead. The ANP program spawned a flurry of activity and investment at INL, which came to a crashing halt in March 1961 when the Kennedy Administration abruptly cancelled it. With the advent of satellites and intercontinental ballistic missiles, the rationale for nuclear-powered flight waned.

One global runway

The Air Force briefly considered Idaho for the operations of the ANP airplane. A 7 km runway was envisioned and a giant hanger capable of handling the radioactive plane and its crew was actually constructed. Today that hanger has been repurposed for classified manufacturing for the U.S. Army. The program established the facility infrastructure at Test Area North, which included the capability to tow highly radioactive experiments by a shielded locomotive to a massive hot cell examination facility, which would have important later application.

Coupling a nuclear reactor with turbojet engines

GE conducted three high temperature reactor experiments (HTRE 1–3) at INL. The first experiment in late 1955, called the Initial Engine Test, proved that a reactor's heat could run a modified J-47 engine. More work was needed to develop fuels and materials for the high-temperature operating regime, but the test specimens were too large for MTR. GE modified the HTRE for irradiating materials in high neutron flux at temperatures of 1500 °C in the HTRE-2 tests. GE built a new HTRE-3 reactor for the next phase, which achieved a major milestone in December 1960 when the reactor started and ran two turbojet engines at 1100 °C.

Plans for managing radiation and contamination

The ANP program addressed challenging radiation issues. If everything went right on a flight mission, the plane would return with highly radioactive nuclear reactor. The shielded locomotive was to move it into the hanger, which had a complex shielded subterranean maze for the crew's egress. SUSIE, the Shield Test Pool Facility, was built at TAN for ANP shielding studies, but served a similar function for later programs. The most unusual experiments were the Fuel Element Burn Tests, better known as the Wiener Roasts, which simulated a crash and a jet-fuel driven fire on the desert floor. The nuclear fuel proved resistant to contamination release.

Powering remote bases

The U.S. Army was also motivated in the 1950s to find nuclear power solutions to operational issues. Given sufficient safety and reliability, small nuclear powerplants would be advantageous for replacing diesel technology that required a steady resupply of diesel fuel in challenging locations. The Army's interest was in small units that could be transported and set up relatively easily, as well as mobile powerplants that could be deployed where needed. With low total weight a priority, the Army pursued BWR technology for the stationary plants and air-cooled technology for mobile units. Idaho's role was one of many activities integrated across the nation.

Army reactor experimental area

Like the Navy and Air Force, the Army got its own INL test site, the Army Reactor Experimental Area, later known simply as ARA. The first test for the mobile units was the Gas Cooled Reactor Experiment (GCRE) designed by Aerojet General Corporation. GCRE went critical in 1959, producing the fuel pin data for the Mobile Low-Power Reactor, ML-1. The first reactor at ARA was the Stationary Low-Power Reactor No. 1, which went critical in 1958. Designed by Argonne National Laboratory and operated by Combustion Engineering, SL-1's mission was to train crews for future reactor operations in the Defense Early Warning Line along the Arctic Circle. Crews were rotated between Idaho and Fort Belvoir, Virginia, where they trained on the prototype Stationary Medium-Power Reactor, SM-1.

Disruptive disaster

SL-1 experienced a lethal accident in early January 1961. The catastrophe destroyed the reactor, contaminated ARA, and forced the ML-1 work to move to Test Area North, home of the cancelled aircraft propulsion program. Results from the ML-1 program were not encouraging, with the reactor not able to sustain power production long enough to reach its performance goals. The following year the Army ended its reactor development program. Apparently undeterred by the SL-1 experience, the Army continued to operate a few small reactor plants in remote locations for several more years. Decades later, there is revived interest in advanced versions of these microreactors to power remote communities and military stations.

Testing the limits of safety

Safety was the compelling argument for locating reactor testing in remote Idaho. The case had two parts—assuring public protection against unexpected radiological incidents and gauging the safety limits of the reactor concepts themselves. Both the reactor designers and the nuclear regulators needed hard data on the practical physical limits of reactor designs, with major emphasis on fuel and thermal properties.

Reactors designed for testing accident scenarios

In simplest terms, reactor safety experiments focus on runaway reactions, such as happened at Chernobyl in 1986, and heat removal once the cooling system is inoperable, such as the case with the Fukushima Daiichi powerplants in 2011. Transient test reactors examine the effects on nuclear fuel when subjected to sudden overpower events. The majority of INL's safety test reactors were of this type. Following the 1979 Three Mile Island nuclear accident in Pennsylvania, emphasis shifted to a reactor facility constructed to investigate loss of coolant flow following reactor shutdown. The materials testing reactors also contributed to the safety database by putting candidate fuels through less severe operational transients of temperature and power. Collectively these tests provided indispensable knowledge for reactor design and licensing.

Transient test reactors

In the earliest transient test reactors, the reactor itself was the experiment. A fairly simple reactor design with the desired characteristics would be subjected to a rapid power excursion, after which the damage would be assessed and analyzed. The Boiling Water Reactor Experiments (BORAX) and the Special Power Excursion Reactor Tests (SPERT) I-III were in this category. Later, more versatile transient test reactors were built to test different types of reactor fuels under varying conditions. The reactors consisted of a driver core and a central region for the targeted fuel. Very rapid power transients could destroy the test articles but had little or no effect on the reactor. The Transient Reactor Test Facility (TREAT), SPERT-IV, and the Power Burst Facility (PBF) comprised this category.

BORAX

No reactor program at INL had a more colorful history than the Boiling Water Reactor Experiments. INL was the only place where scientists could deliberately cause a reactor to blow up to test their predictions. In the early 1950s there was technical disagreement about the potential effect of steam bubbles on a reactor's controllability. Some scientists thought the voids in the core would cause erratic behavior, while others thought that boiling might actually make the core self-regulating, thus preventing accidental overheating. The BORAX experiments tested this theory from 1953 through 1958. BORAX-I and II tested the basic BWR concept using available test reactor fuel. The larger BORAX-III experiment demonstrated the first useful production of nuclear electricity in 1955. At 20 and 40 MW, respectively, the BORAX-IV and V reactors tested high-temperature fuels and higher quality steam for commercial application. DRESDEN-1, the first commercial BWR, started operation in 1960 in Morris, Illinois.

BORAX-I&II

BORAX-I was a simple, open pool-type reactor with aluminum fuel and controls located in a remote trailer. Samuel Untermyer was the main proponent of the boiling water reactor concept, with essential backing and hands-on participation from Argonne Laboratory Director Walter Zinn. From the control trailer, Untermyer could pull a control rod from the core, sending the reactor on a power excursion, spewing steam and water high enough to be visible from the public highway that runs through the site. After more than 200 successful tests that demonstrated self-regulation of reactor power, Untermyer designed the final test to demonstrate

that a BWR could be pushed too far. The test, which blew the reactor apart in a steam explosion, was the first to quantify the impacts of an accident and remove some speculation about the resultant nuclear hazards. BORAX-I became a video sensation (“BORAX” [youtube.com](https://www.youtube.com/watch?v=Ugk1vYUg8j0).) Cleanup of the destroyed reactor was unceremoniously accomplished, and BORAX-II was constructed a short distance away, only to be similarly destroyed in a violent explosion at the end of its useful life. Convinced by the BORAX-I experiments that aggressive safety testing under controlled conditions could provide vital information without disaster, the AEC approved new projects for other reactor concepts, leading to a rapid proliferation of reactors on the desert.

BORAX-III

BORAX-III provided electricity to the city of Arco, Idaho, on July 17, 1955—a nuclear first. The accomplishment would appear simple enough, given a stream-producing 15 MW nuclear reactor and the electrical infrastructure of the INL. However, the project was under intense pressure to be completed prior to the first International Conference on Atomic Energy scheduled for August. Finding and assembling a compatible turbine generator on short notice proved challenging, as did connecting to utility transmission lines. (Haroldson, 2008) Success came at midnight, unknown to most residents, but captured on film by the AEC. The citizens of Arco were invited to view the film on August 12, 1955—the same day that it was shown to the conference delegates in Geneva, Switzerland.

SPERT

Having demonstrated the stability and safety characteristics of boiling water reactors, Argonne transitioned to technical support for their commercialization. The Phillips Petroleum Company took over transient testing for water cooled and moderated reactors, building the Special Power Reactor Excursion Test (SPERT) facility near the Central Facilities area of the site. Thousands of SPERT experiments, conducted between 1964 and 1970, were increasingly more sophisticated than the proof-of-principle BORAX experiments. While each of the four SPERT facilities contributed to power reactor development, they also advanced instrumentation needed to extract data from challenging test environments. SPERT-I tested the damage resistance of low-enriched uranium oxide fuels similar to the type that would be used in commercial powerplants. SPERT-II conducted transient experiments in heavy water systems, providing essential data for reactor development in Canada and Europe. SPERT-III enabled testing under a wide range of temperature, pressure, and flow conditions. SPERT-IV introduced a driver reactor core with central test region, setting the stage for the next generation of transient test facilities.

PBF

The Power Burst Facility (PBF) took over the water reactor safety test program from SPERT in 1972, operating until 1985. It was built during the time at which commercial LWR designs were being scaled by an order of magnitude larger than the AEC-supported early demonstration plants. Safety analysts conjured a new suite of potential accidents for the large powerplants. Experimental data were needed to set safety limits and license these new plants. Sufficiently isolated southeast of the site’s Test Reactor Area, PBF was a large, powerful, versatile test reactor. Capable of large bursts of power within milliseconds, it could simulate a wide range of transients in a central test fuel capsule. But it could also test slower events, such as loss of coolant. Destroyed test fuel was moved to INL hot cells for examination. Data from PBF was a boon for safety code developers. Following the Three Mile Island meltdown in 1979, a PBF simulation accurately predicted the state of the melted core.

TREAT

The first facility constructed at INL’s easternmost site, now called the Materials and Fuels Complex (MFC), the Transient Reactor Test Facility (TREAT) began operation in 1959. Unlike BORAX, SPERT, and PBF, which tested the transient behavior of water-moderated reactors, TREAT was primarily intended for fast reactor fuel research. The reactor is an air-cooled graphite cube, lightly salted with highly enriched uranium, a central test region capable of accommodating sodium or water-cooled test loops as well as simple capsules, and hodoscope slot to allow real-time observation of fuel behavior during a transient test. Capable of a wide variety of transient shapes and operating modes from steady-state to one-second pulses of 20 gigawatts, TREAT conducted hundreds of experiments that led to improved fuel performance and enhanced development of severe accident simulation codes. TREAT claims two bits of history that are unique on the INL site: some of the graphite for its reflector came from CP-1 (Holl, 1997), and after being mothballed since 1994, the facility resumed operation in 2017.

Slow accident testing

While the transient test reactors were capable of simulating some scenarios involving loss of coolant, regulatory interest completely refocused on slow-evolving events following the severe accident at the Three Mile Island powerplant in 1979. Scenarios that took hours or even days to evolve required tests with whole-core involvement, something that could not be fully achieved in the modern transient reactors. Concern about the consequences of a cooling pipe break in an LWR plant began in the mid-1960s as the plant designs began to exceed 1000 MW. While testing in SPERT showed that the fission reaction would automatically shut down due to physics, the worry about a loss-of-coolant (LOCA) accident was that the fuel would fail due to continued heating by decay of the massive fission product inventory in the core. The term “China Syndrome” was coined to describe a scenario in which the molten reactor core bore through the containment into the soil beneath the vessel. A secondary system would be needed to remove the decay heat and ensure adequate safety. In 1963 the AEC initiated planning to test LOCA events in a new facility called the Loss-

of-Fluid-Test (LOFT) reactor in Idaho, a key addition to the Commission's capabilities for its Safety Test Engineering Program (STEP).

STEP stumbles

Initial plans for the LOFT facility followed the typical Idaho script, except that the components would be off-the-shelf, not custom fabricated in INL shops. A small version of a PWR would be constructed, with initial testing of all the non-nuclear components, followed by a destructive event that could be analyzed in detail. Two developments sidetracked these plans. First, the LOFT design incorporated stainless-steel clad fuel rods, just as the industry was changing to a zirconium alloy, which potentially would affect an accident involving high-temperature steam. But the major impact came from a change of direction in the AEC's reactor development program. The AEC shifted emphasis to assuring the highest levels of quality, rigid procedures, transferring responsibility for reactor development to the private sector at the earliest opportunity, and designing redundant engineered safety systems to prevent major accidents. The concept of a dramatic, but unrepeatable destructive experiment did not fit this strategy, causing the LOFT program to drift. STEP progress did continue using an electrically heated facility called Semiscale which was ideal for providing data for codes that analyzed pipe breaks. Unexpectedly, in 1971 Semiscale demonstrated that under some conditions steam pressure would prevent emergency cooling water from reaching the core, raising troublesome issues for licensing large LWR plants. More federally funded safety research was needed after all.

LOFT

LOFT finally got on track in 1974 with a new testing strategy when all safety research was put under a new Division of Reactor Safety Research in the AEC. The facility was redesigned to provide multiple LOCA tests that would inform safety and accident codes. Located at Test Area North, the shielded locomotive was pressed into service to move the reactor between its containment dome and the massive TAN Hot Shop for examination. LOFT's first experiment was a worst-case event—a double-ended guillotine pipe break in December 1978. The emergency core cooling system performed better than predicted, limiting the fuel temperature rise to about 540 °C. A variety of additional tests were planned to provide data for the continuously improving computer models.

The TMI-Idaho connection

Three months after the initial LOFT test, the core meltdown at the Three Mile Island 2 (TMI) caused an abrupt change of plans. The testing program for LOFT and Semiscale shifted from large LOCAs to examination of small leaks and operational transients. PBF results had quickly determined the likely state of the TMI fuel; LOFT focused on the cooling water. Within 2 years, LOFT had successfully simulated the TMI accident, verified the associated safety codes, and attracted international attention to INL's unique safety testing capability. The Organization of Economic Cooperation and Development contributed technically and financially to the program from 1983 to 1986. LOFT testing concluded in 1985 with the deliberate melting of its test fuel bundle, almost as originally planned nearly two decades earlier. The TMI fuel rubble was eventually transported to Idaho for further study and interim storage.

Developing fast reactor technology

From the earliest days of the AEC, nuclear energy leaders anticipated that fast breeder reactors would be deployed as soon as possible, eventually dominating the commercial nuclear market. This assumption was grounded in the belief that uranium was scarce, and the knowledge that thermal reactors could only consume less than 1% of mined uranium ore. On the other hand, breeders could extend the resource by two orders of magnitude. EBR-I was the initial fast reactor, constructed at its namesake site. As development plans matured, all fast reactor work transferred to a more suitable site, now known as the Materials and Fuels Complex (MFC). By 1969 the move was complete.

An integrated research and development complex

The Materials and Fuels Complex had all the facilities, materials, and infrastructure needed for fast breeder reactor development, with capacity to support other nuclear programs. The Transient Reactor Test facility kicked off the operations in 1959. The Experimental Breeder Reactor-II (EBR-II), a 62.5 MW powerplant, supplied electricity to the INL and cogenerated steam heat to the MFC site, while performing fast neutron irradiation services for a variety of programs. The Fuel Cycle Facility recycled used metal alloy EBR-II fuel. The Fuel Manufacturing Facility fabricated fresh driver and experimental fuel. The Analytical Chemistry Laboratory performed detailed analysis of test samples. The Zero Power Physics Reactor (ZPPR) facility assembled 21 reactors varying from small space systems to huge breeder reactors, supplying direct design physics data as well as benchmark data for the International Reactor Physics Handbook Database ("IRPhE Project" [OECD-NEA.org/science](https://www.oecd-nea.org/science)). Starting in 1975, the last major facility, the Hot Fuel Examination Facility (HFEF), supported reactor programs from across INL. The Neutron Radiography Facility (NRAD), a unique feature of HFEF was built in the basement around a TRIGA reactor, which in 1978 was the last reactor added to the INL fleet.

EBR-II: A versatile demonstration platform

EBR-II was to be the first major step toward commercialization of sodium-cooled reactors. Construction started in 1958 with an initial objective to operate reliably using recycled fuel to drive a superheated steam cycle to produce about 20 MW of electricity. Most systems and components were first of a kind, as were the maintenance and operating procedures. EBR-II's unique design enclosed all primary heat transport systems, two centrifugal pumps, a heat exchanger, and a fuel storage basket in a sodium-filled vessel. An electromagnetic sodium pump was used for the secondary sodium loop that connected the in-pool heat exchanger and the steam generator (Koch, 2008). Fuel was handled remotely under sodium within the vessel. Approximately 35,000 fuel pins were melt-refined, recast, and remotely fabricated in FCF for reuse in EBR-II (Stevenson, 1987). From 1963 to 1965 EBR-II gradually increased power to its thermal design rating of 62.5 MW, making modifications as needed. Fuels and materials irradiation testing, in place from the outset, became EBR-II's primary mission in 1969 after the AEC had decided on an accelerated path to rapid fast reactor commercialization. The next test reactor, the Fast Flux Test Facility (FFTF), would be built on the Hanford site in Washington, to be closely followed by the Clinch River Breeder Reactor (CRBR), a 350 MW-electric utility-AEC cost-shared prototype in Tennessee. The AEC directed EBR-II and the other MFC facilities to support those two projects.

Opportunity from chaos

Electric Utilities agreed to fund \$257 million of the \$400 million estimated cost of the CRBR project. The project started in 1972 without the technical support expected from FFTF, which was finally completed in 1978 after extensive delays and cost overruns. The extended schedule delay for FFTF operation gave EBR-II new opportunities as a flexible technology demonstration platform. Advanced fuels, cladding and structural materials were irradiated in EBR-II. From 1975 to 1986 the Run Beyond Cladding Breach (RBCB) program demonstrated that due to innovative technology to remove contamination from the coolant and inert cover gas, sodium-cooled reactors could continue to operate with minor cladding failures. The results of the RBCB program also dispelled the widely held belief that significant cladding breaches would lead to flow blockage or damage propagation. Operational experience demonstrated that the EBR-II design with metal fuel was inherently self-regulating. Many of EBR-II's innovations were picked up by designers in other countries, even though the U.S. decided on a different design approach. Loss of utility interest and an estimated completion cost exceeding \$3 billion contributed to Congress' cancellation of the CRBR project in October 1983. Though jarring to the nuclear community, the sudden cancellation created an opportunity for adapting breakthrough technologies.

The integral fast reactor

Argonne's Associate Laboratory Director, Charles Till, assembled his most gifted leaders to put together a fast reactor program proposal that would address all of the major public concerns about fast reactor technology. Less than a year after CRBR's demise, Till introduced the Integral Fast Reactor Program (IFR) as a complete technical solution (Till and Chang, 2011). Inherent safety was addressed by the proper choice of fuel, materials, and design. Proliferation resistance was inherent in an on-site electrorefining recycling scheme that would not separate refined plutonium. Waste would be compact, with the long-lived constituents remaining in the fuel cycle. The scientific underpinning was already in place through the EBR-II experience. The highlight of the IFR program took place in 1986 when the EBR-II staff executed two landmark safety experiments witnessed by a collection of distinguished international, national laboratory, and industry observers. With safety systems disabled, two severe accident precursor events were initiated. In both cases, the reactor temperature rose slightly and then stabilized. Either event would have destroyed a conventional reactor, but there was no damage to the EBR-II fuel or components. These landmark tests were overshadowed by the Chernobyl disaster 3 weeks later. The IFR program was cancelled in 1994, but not before planting the conviction that advanced reactors could be designed to be impervious to accidents under almost all conditions.

Unplanned accidents

The brilliant minds of the 1940s knew that they didn't have all the answers. The best protection for the public while the AEC pursued those answers was to locate experiments for the new, the untried, and the unestablished limits of safety well away from population centers. The Idaho site was the location of two notable unplanned accidents.

SL-1

In early January 1961 the SL-1 reactor explosively disassembled, killing all three technicians on late-night duty. The resulting contamination spread over several kilometers. The cause of the accident was extensively studied. Design shortcomings, procedural violations, and inadequate maintenance may have each played a role. This was the only deadly accident in U.S. nuclear powerplant history.

EBR-I

The EBR-I highly enriched uranium core has been described as about the size of a football. During a transient experiment in November 1955, about one-half of the core melted. As horrific as a core meltdown may sound today, it was a manageable incident. The damaged core was packaged, sent to Illinois for examination, and replaced with a new one.

Fuels and materials development

No INL reactor activity has been more sustaining, varied, and impactful, nor required more ingenious solutions, than fuels and materials development. It is actually the only reactor activity that has continued unabated for almost 70 years. While this is an enterprise broadly distributed across industry and research laboratories, the irradiation and examination of samples are centered in Idaho. Through clever design, this class of test reactors can substantially accelerate aging in materials and fuel samples.

Idaho's irradiation facilities

The Materials Test Reactor, one of the original big four, operated from 1952 to 1970. As with other first reactors, it was its own experiment, demonstrating plate-type fuel for future test reactors. It also demonstrated plutonium-based driver fuel at a power level up to 30 MW. The 175 MW Engineering Test Reactor was a more powerful and versatile experimental reactor that operated between 1957 and 1982. A sodium cooling and a helium cooling system were added in order to accommodate tests for a broader array of concept fuels. The 250 MW Advanced Test Reactor (ATR) began operating in 1967 and is expected to continue as long as needed. In addition to its fuel testing services, ATR produces isotopes for medical and industrial applications. From 1965 through 1994 EBR-II served as fast-spectrum fuels irradiation facility, servicing a variety of customers including the fusion program.

Notable fuel development

Given the tens of thousands of experiments in INL's materials testing reactors, it is impractical to catalogue all the fuel concepts that have passed through. Idaho's unique capabilities for examining irradiated material, in whatever detail necessary, provides the data that are actually applied in production and licensing. Four accomplishments illustrate the impact. Naval Reactors Program is the main customer of ATR; it has developed fuel that lasts for the entire 30-year life of a submarine. The IFR ternary uranium-plutonium-zirconium metallic fuel is the reference for whatever U.S. fast reactors are developed in the future. Several variants of Fukushima-inspired accident-tolerant LWR fuel under industrial development are being tested in Idaho. A reliable tri-isotopic (TRISO) high-temperature fuel has been qualified for use in helium-cooled, water-cooled, or molten-salt reactor applications.

Powering space exploration

Since its inception in 1958, the National Aeronautics and Space Administration (NASA) has been intrigued about the possible mission-enhancing benefits of nuclear power. Numerous universities, NASA research centers, and DOE national laboratories including INL have been engaged. Three types of nuclear systems have been investigated at various times: nuclear rockets for human exploration of the solar system; tiny reactors for power-intensive satellites; and long-lasting, reliable radioisotope thermoelectric generators (RTG). INL played a significant, but not dominant role in each of these technology programs.

Nuclear thermal propulsion

From 1967 to 1972 INL conducted cavity reactor critical experiments at the Test Area North to determine whether a gaseous uranium core surrounded by flowing hydrogen could achieve criticality. Simulants were used in the low-power, low-temperature experiments. Temperatures in this ambitious concept's gaseous core were expected to reach as high as 50,000 °C. During the following decades INL had little direct involvement with NASA's nuclear propulsion concepts until fuel testing in TREAT began in 2019. The current propulsion concept expects the engine to run several times for a few seconds at 3000 °C, parameters that can be readily achieved in a TREAT transient experiment.

Reactor-powered satellites

Russia and the U.S. both had an infatuation with reactor-powered satellites. Russia launched 31 of them between 1967 and 1988. The U.S. launched a single reactor, SNAP-10A, which operated for about a month. NASA's major safety concern was having the highly enriched uranium system crash into the ocean, possibly causing a runaway reaction and substantial radiation release. During the mid-1960s, INL destroyed three SNAP-10 reactors at Test Area North in order to characterize the radiation release from accidents. During the mid-late 1980s, NASA pursued development of a 100 kW-electric space power system called SP-100 that could be used for nuclear-electric propulsion or stationary power. Critical experiments to support the basic concept and the ground test facility

were conducted in ZPPR in 1986 and 1988–89. The tests included simulating accident scenarios such as water immersion and being imbedded in sand. Development of SP-100 was terminated due to the estimated high cost to completion.

Radioisotope thermoelectric generators

Radioisotope thermoelectric generators, better known as RTGs, have been an integral part of NASA missions for almost six decades. The NASA RTGs generate heat by the radioactive decay of plutonium 238. In the early 2000s, the Department of Energy terminated RTG assembly, testing and transportation at Mound, Ohio, and reestablished the capability at the Materials and Fuels Complex in Idaho. INL subsequently provided the RTG for the Pluto New Horizons mission and the Mars Science Laboratory Curiosity rover. In 2019 INL began preparing the RTG for NASA's Mars 2020 mission.

The arc of reactor history in Idaho

Understanding the rise, fall, and possible rebound of Idaho's civilian reactor programs requires putting the events into a national context. The Naval Reactors Program, with its own imperatives and stable funding, had an independent, illustrious trajectory.

Naval reactors program

Although public information about naval reactors is limited, the program has maintained a visible INL presence from the outset. Major achievements include the spinoff of PWR technology to private industry, providing thousands of well-trained operators to nuclear utilities, and developing submarine reactors that don't require refueling during the ship's lifetime. In order to accomplish the later, the naval reactors program dominated fuels and materials testing in ATR.

Rapid growth of test reactors

In the 1950s Americans were fascinated with the promise of atomic power just as electricity demand accelerated in the post-World War II era. In Congress the Joint Committee on Atomic Energy streamlined financial support for nuclear development. The race for nuclear reactor commercialization and technology applications was on; reactors mushroomed in the Idaho desert. By 1960 twenty-three reactors were operating in Idaho, with five more already shuttered. Most of these reactors were built quickly and inexpensively, not intended for long-term use. Technology shakeout favored PWR and BWR development for the near term.

Shift to commercialization

From 1960 through the early 1970s, the AEC focus shifted to the Power Demonstration Reactor program. The number of INL's operating reactors dropped to 17, despite the addition of 15 new units that supported physics, safety, and space research. Culled projects included the beryllium-oxide moderated reactor and the organic-cooled/moderated concepts, while demise of the aircraft propulsion program and the army program terminated several INL reactors. INL's two most venerable reactors, EBR-II and ATR, started operating during this era.

Rise and fall

Significant reactor program activity from the 1974 through 1986 belied the future for INL. Major political changes affected the mission and funding of the laboratory. The Energy Research and Development Administration (ERDA) and the Nuclear Regulatory Commission (NRC) replaced the AEC. The Joint Committee on Nuclear Energy, a stalwart bi-partisan supporter of nuclear development, was abolished in 1977, the same year that the Department of Energy replaced ERDA. With broader energy, science and weapons research portfolios, neither ERDA nor DOE built new test reactors. In 1975 cancellations exceeded new orders for commercial nuclear plants. The last new order in the 20th century was in 1978. With safety experiments winding down by 1986, INL's reactor program future was fading.

Loss of mission

The next 10 years brought an end to INL's civilian reactor development. Anti-nuclear sentiment in the Clinton Administration prevailed. IFR development was terminated in 1994. By 1998, the already shrinking national nuclear research and development budget was eliminated. The Navy no longer needed to train sailors in Idaho. INL's new mission was to decommission facilities and prepare radioactive waste for disposal. Only ATR, with its naval research mission, and two small support reactors remained in operation by 1996. INL's definitive 50-year history ([Stacy, 2000](#)), published at the end of the 20th century, could be read as a 375-page obituary for Idaho's reactors. But with more than 100 commercial reactors operating across the U.S., some national laboratory capabilities were still needed, including regulatory support. National laboratories and universities rallied to put together a reactor research plan for the 21st century.

Mission restored

With his nuclear budget vanishing, William Magwood, IV, then-Director of DOE's Office of Nuclear Energy, crafted a long-range advanced nuclear development plan with his counterparts in France and Japan. The Administration and Congress backed the idea of a multi-national effort to develop 4th generation reactors, possibly leapfrogging the third generation which had yet to be built. The Generation 4 International Forum held its inaugural meeting in January 2000. National laboratories, corporations, and universities set to work on advanced reactors that would meet a robust set of inherent safety, economic, sustainability and nonproliferation goals. Reminiscent of the 1950s, feasibility studies were launched for sodium, lead, helium, molten salt and supercritical water-cooled systems. Magwood then set about consolidating R&D contracts in Idaho, creating a new national laboratory with the Office of Nuclear Energy as its principal sponsor, leaving the decommissioning activities to a separate contractor and DOE office. The Idaho National Laboratory officially began operating in 2005 under the Battelle Energy Alliance.

Stability and purpose

During the next decade, INL matured into its role as a multi-program national laboratory, still focused on nuclear energy, but with significant expertise and funding in cyber security, integrated energy systems, battery technology, supercomputer applications, and biofuels science. Fuels and materials research evolved sophisticated computational capability on the macro, *meso* and micro levels, supported by characterization of irradiated samples at similar levels of detail using new instruments and facilities. Cooperation and coordination became the new norm in nuclear research as public-private partnerships supplanted most government-only R&D funding. More than 40 companies began pursuing advanced nuclear systems. With ATR as its centerpiece, INL coordinates the National Scientific Users Facility (NSUF) to conduct hundreds of research projects for qualified applicants in 50 partner facilities across the U.S. INL also partnered with Argonne and Oak Ridge National Laboratories to create DOE's Gateway for Accelerated Innovation in Nuclear (GAIN), whose aim is a radical reduction in development time for nuclear technology.

Back to the future

As INL celebrated 70 years of landmark nuclear research, the laboratory planned for impactful reactor facilities once again to rise in the Idaho desert. Transient testing resumed at TREAT in 2017. NuScale Power and Utah Associated Municipal Power Systems were moving forward with plans to build a powerplant consisting of 12 small modular reactors on the site in the mid-2020s. One of the modules is planned to be set aside for the Joint Use Power Module project, which will enable research on more efficient ways to utilize a reactor's thermal energy. DOE announced plans to build a Versatile Test Reactor in Idaho or Tennessee for fast spectrum irradiations. INL's 70th year celebration event included DOE's announcement of the creation of the Nuclear Research Innovation Center (NRIC), which could host reactor demonstrations within a few years. NRIC demonstrations will be funded in whole or in part by the private sector. NRIC could be the National Reactor Testing Station reincarnate, with a fresh focus on economic competitiveness and rapid deployment of advanced technology.

Introduction

This survey will briefly address the conceptualization world-wide of the fast neutron spectrum reactor (fast reactor). Liquid metal fast reactors are the most common system, and typically can be separated according to coolant constituent (sodium, sodium-potassium eutectic, lead or lead-bismuth eutectics, etc.), heat removal systems (pool vs. loop), fuel type (oxide vs. metal), and fuel composition (plutonium, uranium, MOX, etc.). As the early reactors were introduced, most every combination of the above have been tested. As the survey is presented, these important characteristics will be highlighted where possible.

The promise

The early promise of the fast breeder reactor was one of virtually unlimited fuel through breeding of fissile fuel in fertile blankets composed of depleted uranium or thorium ([Shusterman, 2020](#)). The ability to achieve a breeding ratio (ratio of fissile fuel produced by neutron capture in fertile fuel to fissile fuel consumed) of greater than one was demonstrated quite early by some of the first reactors like EBR II and Phenix. The EBR I reactor was fueled with enriched uranium and was able to obtain a ratio of just about one.

Overview of design differences

Coolant

The most common coolants have been various liquid metals, such as sodium or lead. They were chosen for their low moderation power and usually very high thermal conductivities. For example, the thermal conductivity of sodium is roughly 120 times that of water at 200 °C, and heat removal is not as sensitive to turbulence in the coolant. That has given liquid metal reactors some safety advantages in a transient situation. A partial list of liquid metal coolants is: sodium-potassium (EBR I), sodium (EBR II), lead or lead-bismuth (Soviet nuclear submarines of the 1970s) and even mercury (Clementine). There are also some fast reactor designs proposed using helium or molten salts, but these have not had wide-spread favor. In fact, by far the most common coolant choice has been sodium in spite of its chemical reactivity. Because of this, most of the discussion below will consist of sodium cooled reactors, although the Soviet experience with lead-bismuth eutectic will be briefly discussed. See also ([Heidet, 2021](#)).

Loop or pool?

In the loop system, several parallel sodium circuits pump sodium through the core to remove heat. Each circuit goes to a separate intermediate heat exchanger (IHX) which is still inside the reactor building. The secondary loop then goes out of the reactor building to a steam generator building, which then goes to the turbines, etc. for power generation. Thus, for safety reasons sodium reactors consist of three loops ensuring that any possible sodium-water reactor would be out of the reactor building. However, this can escalate the cost and complexity of sodium cooled reactors.

The pool system differs in that the primary pump and IHX are contained within a large tank of sodium. The primary pump forces sodium up through core where it is discharged over the IHX. The IHX then transfers heat from the tank which goes to a secondary loop passing outside the reactor building to a steam generator, etc. EBR II was a pool system; the secondary sodium was pumped by means of an electromagnetic pump while the primary pumps in the tank were centrifugal.

It is debatable which system is better ([Kohler et al., 1990](#)). The tank system has an advantage of inherent heat removal just through conduction in the event of pump failure as might happen in a loss of on-site power accident. A series of such experiments were performed in EBR II in the late 1980s demonstrating inherent safety ([Planchon et al., 1987](#)).

Fuel type

Fuel can be characterized by isotopic composition, including fissile enrichment, and structure (metal vs. oxide or nitride). Composition is usually plutonium or uranium, or a mix (MOX or separate oxide elements). The primary reason that SFRs feature higher HM inventory per unit core volume is to achieve hard spectrum—good neutron economy (high breeding gain). The need to use higher enrichment than in LWR is due to the smaller fission cross section. It is possible to design a fast reactor with less than 20% enrichment (% fissile out of fissile + fertile isotopes), but in the early years enrichments were above 50%. The metal fuel has distinct advantages in its heat transfer capabilities and its easy fabrication relative to oxide; metal fuel can be cast and in fact was the basis for the Integral Fast Reactor (IFR) concept developed at Argonne National Laboratory. Metal fuel was the choice of the early fast reactors such as EBR I, EBR II, and Dounreay Fast Reactor (DFR) in Scotland. However problems with swelling led to the adoption of the oxide fuel type which also has a much higher melting point than metal. Balancing that is the superior heat conductivity of metallic fuel, so one can argue that the safety arguments cancel each other out. Metal fuel also offers the highest possible fissile fuel (uranium, plutonium, etc.) density and enables one to design the core to have a harder neutron spectrum and, therefore, better neutron economy. While the world at that point was concentrating on oxide fuels in the late 1980s and 1990s, new designs demonstrated that the swelling problems could be mitigated by using sodium bonding of the fuel to the clad, and having a large plenum above to accept expansion due to swelling (Till and Chang, 2011; Porter, 2021). Thus the metal fuel was a key component of the IFR.

The early years

Clementine

According to Los Alamos reports, Clementine was the world's first plutonium fast reactor (Bunker, 1983). Construction was begun in 1946 under the direction of Phillip Morrison. Apparently, he named the reactor after the song, "My darling Clementine" which has the line "in a cavern, in a canyon." The reactor site was in one of the Los Alamos canyons, and to Morrison the workers were modern '49ers. Additionally, 49 was code for Plutonium-239 (94 protons, 239 nucleons). The fuel was plutonium rods clad in steel, and the coolant was mercury. The core had a six-inch natural uranium reflector followed by an additional 4 in of steel and 4 in of lead shielding. Reactor control rods were fueled, thus withdrawn to achieve criticality.¹ Although criticality was achieved early, actual construction was not completed until March of 1949 and the reactor was operated at 25 kW. (Note: fast reactors can achieve criticality without any coolant, and startups as dry critical are common.) Several shutdowns were necessary due to fuel problems, and at the last one in 1952 it was discovered that fuel had leaked into the mercury coolant. The decision was made to disassemble the reactor completely at that time. During its short life, 41 total cross-section values were measured at Clementine to an accuracy of 10% and over an energy range of 3 eV to 13 MeV. These data provided valuable information to the Los Alamos weapons designers. Additionally, engineering contributions were made to the fast reactor program in general. For example, mercury turned out to be a bad choice for a coolant because of its poor thermal properties.

EBR I

EBR I first went critical in 1951 at the National Reactor Testing Station, now known as Idaho National Laboratory (INL), in December of that year it demonstrated the first production of useable electricity from nuclear power by lighting four 200 W light bulbs (Westfall, 2004; McFarlane, 2020). To be fair, the first actual electricity was produced at the Graphite Test Reactor at Oak Ridge in 1948, by generating enough steam to run a toy steam engine and light a small Christmas tree bulb, but EBR I was the first reactor to have a complete heat removal and electricity production system. The reactor coolant was a sodium-potassium eutectic (NaK). The core, highly enriched U-235 metal, clad in stainless-steel was very small (football size). The core was surrounded by a natural uranium blanket. EBR I had a total thermal power of 1.4 MW and generated 200 kW of electricity (actually enough to power the site). It operated from 1951 to 1963 and was then replaced by EBR II also at the INL, although at about the mid-point of its operating years an operator error during an experiment led to a core meltdown/destruction. The core was replaced rather quickly and operations continued. EBR I served its mission well demonstrating the possibility of a fast reactor producing electricity. It was able to demonstrate a breeding ratio of about one, which is probably close to the limit of a U-235 reactor surrounded by a simple blanket. Using Pu-239 would significantly improve the breeding ratio, and various mixes of U-238 in the core region would also help.

¹The criticality, or multiplication, of a reactor is controlled by altering the neutron balance. If there are more neutrons in a given generation than the preceding generation, the power will increase. The neutron balance is controlled by sources and losses; we can alter this by changing the losses (leakage or absorbent materials inserted into the core), or changing the source of neutrons by inserting fueled control rods. The latter method is used when neutron economy is important, as in a breeder reactor.

Other early reactors

In the Former Soviet Union, the physicist A.I. Leipunsky recognized the favorable neutron balance of the fast system, and began to study the possibilities (IAEA, 2012). He led the effort to develop the fast reactor there, BR 5 was one of the first constructed in 1959. In contrast to other types around the world, the Soviet design utilized PuO_2 as the fuel type instead of metal. BR 5 (5 MWth loop type) operated from 1959 having had two major upgrades over its lifetime, including replacement of the vessel and components of the primary circuit. It operated with nitride fuel in its later years. The mission had been mostly materials irradiation and instrumentation testing, although there were some cancer treatment experiments and fission product release experiments over its years. Leipunsky also oversaw BOR 60 and BN 350 (their first prototype) which was built on the Caspian Sea in what is now Kazakhstan. The BR 10 reactor was shutdown in 2002.

The growth years

EBR II

EBR II followed the success of EBR I, its predecessor. Initial design was essentially complete in 1956, and an architectural engineering firm, H.K. Ferguson, was chosen (Westfall, 2004). Funding for construction was authorized in 1957, and construction begun with Chicago Bridge and Iron being the lead. The first dry critical experiments were begun in December 1960 while the heat transport system was being constructed and tested. The reactor had its first wet criticality in November 1962. After a long period of testing, the reactor was brought to 30 MW in August 1964, and incremented to its final thermal power of 62.5 MW by September 1969. The original mission of EBR II was to further demonstrate breeding based on the experience of EBR I, to be a complete power plant, and to operate as a closed fuel cycle. To that end, the Fuel Cycle Facility (FCF) was constructed adjacent to the reactor building, and a complex cask system developed to move hot spent fuel into FCF for processing and recasting into fuel elements to go back to the reactor. That phase of the mission was completed, and in the 1970s the reactor was used primarily as a fuels and materials test reactor, including testing fuel developed for the Fast Flux Test Facility (FFTF). With breeding demonstrated, the inner blanket region was changed from U-238 to a stainless-steel reflector. In the 1980s the mission changed again, and EBR II became an important component of the Integral Fast Reactor (IFR) program. As part of that program, two landmark tests were conducted in April 1986: (1) loss of flow without scram, and (2) loss of heat sink without scram. In both tests, the reactor experienced mild temperature transients but the reactor shutdown due to strong negative reactivity feedback (Planchon et al., 1987). Ironically, the Chernobyl accident occurred just several weeks after the EBR II tests. In spite of the technical successes, the reactor and the entire IFR research were terminated by Congress in 1994, and reactor operation ceased on September 1994.

Dounreay fast reactor (DFR)

This test reactor, located in northern Scotland, was a loop-type reactor. It was designed to produce 60 MW thermal power and 15 MW electrical power, very similar to EBR II (Metz, 1976). Construction began in 1958 and the reactor achieved its first criticality in 1959. It exported electricity to the UK National Grid beginning in October 1962 until its shutdown in 1977. It was replaced by the Prototype Fast Reactor (PFR) which went critical in 1974 at the same site. PFR is described in the section on prototype reactors.

Rapsodie

Rapsodie was the first step in the French breeder program (Zaleski, 1980). The design started in 1957 and construction began in 1962 at the Cadarache site in southern France. It achieved its first nominal power level of 20 MW thermal in 1967. The fuel was a mixed plutonium and uranium oxide. It had a very simple heat removal system; heat was released to the atmosphere via sodium-air heat exchangers. The power level was increased in several steps ending up at 40 MW in 1971. From 1967 to 1976 Rapsodie operated virtually continuously with about a 90% capacity. It was shut down for about 6 months, upgraded, and operated again until closure in 1982. In April 1994, a fatal explosion occurred during neutralization of some residual sodium. A multi-stage cleaning process using ethylcarbitol was used creating over time an explosive mixture that ignited (Marmonier and Del Negro, 1995).

SEFOR

The Southwest Experimental Fast Oxide Reactor (one loop, mixed oxide plutonium uranium fuel) operated for a very short time, 1969–72 (Hixson, 1972). As the name suggests, it was fueled by MOX and no electricity was produced. SEFOR used a reflector control system: nickel reflector segments were dropped below the core for shutdown, and brought up for operation. Pre-operational testing began in May 1968 continuing until April 1969. The facility had a fairly specific set of objectives for a three-year experimental program: (1) to determine the physics parameters of sodium-cooled fast oxide reactors, particularly concentrating on Doppler and other quantities important to safety, and (2) to demonstrate the reactor operating characteristics. To these ends, four phases were planned and executed which included static testing, oscillator experiments, delayed-critical transients, and prompt-critical transients. Upon completion of the program, the reactor was shut down in 1972. The site was taken over by the

University of Arkansas after nuclear material was removed and used for research purposes until 1986. The University finally received decommissioning funding from the Department of Energy (DOE) and dismantling was completed in 2019.

BOR 60

BOR 60 was commissioned in 1967 designed for 60 MW thermal and 15 MW electrical (very similar to EBR II and DFR). Its fuel is MOX, with highly enriched uranium. BOR 60 has served mostly as a fuels and materials irradiation facility (Trojanov et al., 1990) serving as a testbed for new fuels before going into BN 350 or BN 600. Vibro-packed MOX fuel has been tested in this reactor, and an extensive structural materials irradiation program conducted, concentrating on low-swelling ferritic steels. Additionally, cesium traps with graphite as absorbent have been tested and refined in this reactor, and knowledge applied to BN 350 and BN 800. BOR 60 is still operating after 50 years and will likely stay operational until the MBIR (a ‘multi-purpose sodium cooled research reactor’) is completed.

Joyo

Joyo is a 100 MWth fast reactor in Japan, operating since 1977 (Sawai et al., 1990). It has been used as a fuel and material irradiation facility as well as a test bed for other components of the reactor. Its fuel is a plutonium-uranium oxide mix enriched to a little over 20% at equilibrium. Joyo has been used to test decay heat removal by natural convection as part of a program to demonstrate inherent safety of fast breeder reactors. Joyo is in a temporary shutdown following a general slowdown in reactor development in Japan particularly following the Fukushima accidents; however, the decision has been made to decommission its planned successor (Monju) but continue research at Joyo (NEI, 2016).

Some prototype reactors

Fermi 1

The Fermi 1 reactor was designed to be a 400 MWth reactor, but with its first (and only) core it only generated 200 MWth with 61 MW electric. It was built by and operated by Detroit Edison to be the U.S.’s first prototype breeder reactor. Construction began in 1956, and first criticality achieved in 1963. However, the facility was beset with many problems and useable power not generated until 1966 (Reindl, 2016). Within months, a zirconium catch plate had broken off and partially blocked some of the coolant inlet flow plates causing two fuel subassemblies to partially melt (about 1% of the core). The reactor was immediately shut down, and there was no subsequent radioactive release beyond the containment building. It still took almost 4 years to investigate the problem, remove the damaged subassemblies and restart the reactor. The reactor then began operation, generating an overall modest amount of electricity until the core hits its burnup limit in 1972. At that point the utility decided to permanently shut the facility leaving the U.S. with no operating prototype fast breeder reactor. Fermi 1 was to be followed by the demonstration reactor, the Clinch River Breeder Reactor (CRBR) but that project was canceled in the early 1980s.

BN 350

BN 350 could be considered the world’s first (successful in contrast to Fermi 1) industrial scale breeder which was also used to power a large desalination plant. The reactor is located on the Mangyshlak Peninsula in the Former Soviet Union country, Kazakhstan, on the Caspian Sea. It is located on the site of a “secret uranium mining center” (Guth, 2018). The design was started in 1960 and the reactor first went critical in 1972. It was connected to the grid in 1973 and initially operated at powers of around 300 MWth until issues with the steam generators as well as other start-up problems were solved. From about March 1975 to January 1996 it operated at a 650–750 MWth level at around 90% capacity (IAEA, 2006). Leaks in two of the steam generators cause water incursion into the sodium, so two out of six loops were taken out of service and the plant derated to about 420 MWth. It was permanently shutdown in April 1999. One of the original goals of BN 350 was to be a testbed for improvements in burnup. It started with around 9% burnup (fissioning ~9% of the loaded heavy metal) and gradually improved that to better than 12% through introduction of various martensitic-ferritic steels for subassembly and fuel wrappers (Trojanov et al., 1990). To help flatten the power profile, the core had three zones of enrichment, from 17% to 21%. Various fuels of plutonium, uranium, and MOX were tested over the years feeding valuable data to its follow-on power reactor, BN 600.

Phenix

Phenix was also a successful prototype, built and operated in Marcoule, France (on the Rhone River near the city of Orange). It was a 250 MWe pool-type with three secondary loops and modular steam generators (Carle, 1973). The design began in 1964, construction in 1968, and operation commenced in 1973 followed by so-called industrial operation in 1974 (Zaleski, 1980). Following a few years of startup problems with the steam generators in particular, in April 1978 Phenix achieved full operating power and continued to run for years at typically 85% capacity factors. In the beginning, operation of the pool-type reactor proved to be “easy,” which was one of the early objectives of the facility. The reactor was rated at 590 MWth over a core volume of 1200 L. It

demonstrated a breeding ratio of 1.12 with PuO_2 fuel. Because of the higher coolant temperatures, the reactor operated with a thermal efficiency of 44% (Kohler et al., 1990). Operation could be divided in roughly three phases: (1) 1974–90 Demonstration of Na cooled FBR technology, (2) 1990–93 Investigation of reactivity transients, and (3) 1994–2002 Renovation with two full operating cycles. From 2003 the reactor was derated to 350 MW operating with only two secondary circuits. It was shutdown in 2009 and is in the decommissioning phase. Phenix was followed by Superphenix, a large technological step at 1200 MWe.

PFR

The Prototype Fast Reactor (PFR) was located at Dounreay, UK (northern Scotland). It began operation in 1975, designed for 250 MWe and 630 MWth (Jensen and Olgard, 1995). It was shutdown in 1994. The active core was 0.915 m in height, 1.47 m diameter yielding a core volume of around 1500 L. It was fueled with a combination of PuO_2 and UO_2 with an inner zone enrichment of 23.5 w/o (Pu) and outer zone enrichment of 32 w/o (Pu). The reactor was a pool-type with three primary and three secondary loops. Above and below the active core was a depleted uranium blanket, a radial blanket surrounded the core as well. The original target burnup was 7.5% (heavy metal) but through improvements in cladding and plenum designs 15% was achieved. Operation of PFR can be grouped into two phases (IAEA, 2006). In the first decade, operation was plagued by steam generator leaks (37 in all) preventing any load factor from exceeding about 12%. After 1984 most of the problems were fixed through improvements in welding and other design changes, and the load factor increased to about 57%. In 1985, the facility could operate with a full set of steam generators for the first time. In this second (and last) decade of operation there was only one major outage of 18 months caused by leakage of oil from the primary pump into the sodium. This occurred in 1991; the reactor was operated for the last time in 1994.

Russian submarine reactors

While they fall outside of the definition of test reactors, we mention the lead-bismuth eutectic systems used by the Soviets for submarines from the mid-1960s to the mid-1990s because of the importance of their design and operating experience with a promising reactor type for the next generation of advanced reactors. In the period mentioned above, the Soviets built 12 reactors and 15 cores and accumulated 80 reactor-years of operations (Alemerti et al., 2014). While the U.S. chose sodium as the coolant for their first liquid metal submarine reactor (Sea Wolf) because of problems with lead-bismuth corrosion, the Soviets invested the time to solve the problems. They ultimately succeeded mostly through better engineering of coolant systems and better control of the coolant chemistry (Zrodnikov et al., 2000). The advantages are the very high boiling point of the lead-bismuth eutectic and its chemical inertness, in contrast to sodium on both counts. Lead-bismuth reactors do not suffer from positive reactivity void coefficients because of the high boiling points. Also the very low absorption of the coolant allows the reactor to operate with less excess reactivity (fuel mass). There were three accidents that resulted in the reactor systems being unusable, but only one is directly attributable to the actual coolant type. That occurred in 1968 when the formation of lead oxides accumulated in the core causing local coolant blockage. A series of events lead to partial core meltdown. The solution was better oxygen control of the primary system. In the last 10 years of operation there were no further problems due to corrosion or purity control.

It is true that the lead-bismuth eutectic reactor does produce Polonium-210, a dangerous alpha emitter with a 138 day half life. However the Soviets found that the creation of aerosols would be the main source of release and transport of polonium is mitigated by rapidly lowering the temperature and solidifying the eutectic. Also the low concentration of polonium in the system leads to the formation of polonium-lead compounds which reduce the polonium pressure by a factor of 1000.

Other reactors

This survey has attempted to focus on the pioneer facilities both in the experimental reactor and prototype reactor phases. Additionally, some reactors that were purely fuels and materials test reactors, with no electricity generation, have not been highlighted. Notably, there is no description of the Fast Flux Test Facility (FFTF) which operated at 400 MWth from 1980 to 1992, but Joyo in Japan is described because Joyo is Japan's first experimental fast reactor. If one is interested in more information there is a comprehensive list compiled by the IAEA and available as a technical document (IAEA, 2006). Additionally the World Nuclear Organization maintains a searchable database.

Summary

Mixed success

It is fair to say that the fast reactor program has a mixed record regarding its development as a commercial power source. There have been some successful programs, notably EBR II which was well on its way to becoming a test facility for the advanced IFR program until it was canceled by the U.S. Congress in 1994. Some had very difficult start-up periods (cf. Phenix and PFR), often with steam generator problems exacerbated by the sodium/water boundary that must not be breached. Fermi 1 suffered a partial core melt

within the first few months of power operation. And although Phenix is considered a success, it did turn out to be much more expensive to construct and operate than originally envisioned.

Early cancelations or closure

In the U.S, the CRBR never made it to the final design stage before being canceled by Congress. The Monju reactor in Japan suffered a series of accidents starting with a sodium fire in 1995 that prevented any significant hours of electricity production since the first criticality. In 2016 the decision was made to decommission the reactor. The SNR-300 reactor in Germany was constructed, but never operated. Finally Superphenix in France, a very large step from the successful Phenix, was closed in 1997 by the French government after a number of years of mishaps, including a roof collapse in an auxiliary building due to snow load.

Future

At the present time there is not much need for a breeder reactor so it is likely that the future of the fast reactor lies in its use as a fuels and materials test reactor. The inherently higher fast neutron fluxes allow accelerated testing of advanced fuels and materials in support of the extension of the current LWR fleet as well as in support of Gen-IV systems if any country decides to actively pursue such systems. Examples are Joyo (which has survived while Monju has not), the MBIR under construction in Russia, the planned Versatile Test Reactor in the U.S. and Astrid (in France).

Summary Table.

Reactor	MWth	Fuel	Coolant
Clementine	0.025	Pu	Hg loop
EBR-I	1.2	U	NaK loop
BR-5	5	PuO ₂ -UO ₂	Na loop
EBR-II	62.5	U-Zr	Na pool
DFR	60	U-Mo	Na loop
Rapsodie	40	PuO ₂ -UO ₂	Na loop
SEFOR	20	PuO ₂ -UO ₂	Na loop
BOR-60	55	PuO ₂ -UO ₂	Na loop
Joyo	100	PuO ₂ -UO ₂	Na loop
Fermi-1	200	U-Mo	Na loop
BN-350	750	UO ₂	Na loop
Phenix	560	PuO ₂ -UO ₂	Na pool
PFR	650	PuO ₂ -UO ₂	Na loop
Soviet submarine	155	–	Pb-Bi loop

Introduction

Transient reactors are a unique branch of materials test reactors designed for investigation of material behavior that rapidly evolves in extreme nuclear environments. While many of these facilities have been and continue to be used for the study of nuclear physics, most are dedicated to the investigation of reactor and fuel safety research. These test reactors played a particularly prominent role in the early days of nuclear technology development when the foundation of reactor safety was being set. As light water reactor (LWR) technology matured and become widely implemented, the need for transient testing waned and many facilities were decommissioned. However, a resurgence in advanced reactor technology development and exploration into higher performance LWR fuel designs has returned these facilities to the forefront of the field (Wachs, 2012).

Licensing of nuclear fuels for reactor applications requires empirical demonstration of their performance limitations and confirmation that those limits are not exceeded during all anticipated operating occurrences (AOOs) and design basis accidents (DBA). The nuclear regulator community often extends this exploration to include fuel behavior under severe accident conditions. In all cases, transient testing reactors are essential to replicate this unique nuclear environment and, thus, empirically demonstrate the relevant behavior in the most prototypic environment possible.

The Idaho National Laboratory's (INL) Transient Test Reactor (TREAT) facility shown in Figs. 1 and 2 is a foundational piece of the U.S. advanced fuel technology development and licensing enterprise. Constructed in 1959 (Freund et al., 1958; Pope et al.,

Fig. 1 Aerial photograph of the Transient Reactor Test (TREAT) facility.

Fig. 2 TREAT reactor layout.

2019), TREAT was one of the world's earliest nuclear reactors and was the first to be dedicated to nuclear fuel safety testing. TREAT conducted thousands of experiments in the following decades and helped form the basis for the reactor fuel safety limits still applied worldwide in both commercial power generating stations and research reactors. TREAT was also critical in the evolution of fuel systems projected for use in advanced reactor concepts, sodium-cooled fast reactors (SFR) in particular. This significant versatility across multiple reactors types, in spite of TREAT's thermal neutron spectrum, is due to the fact that fuel safety testing is driven by the study of thermal-mechanical response of fuel systems to time dependent fission energy deposition. Thus, spectral effects are relatively unimportant when compared to testing under steady operating conditions.

However, after enabling decades of critical nuclear research and development, TREAT was placed in standby mode in 1994 due to massive reductions in U.S. nuclear energy research funding. TREAT was subsequently returned to operation in 2017 (Bumgardner and Wachs, 2019; Heath and Race, 2019) following a remarkable resurgence in interest in both enhanced fuel designs for LWR and advanced reactors applications.

TREAT is designed to deliver a wide array of nuclear transients that mimic expected and hypothetical events of interest to nuclear fuel and reactor technology developers. These nuclear transients are complemented by the ability to insert experiment specific test rigs into the reactor that are capable of simulating whatever unique thermal hydraulic environment that is required to mimic the reactor system of interest.

Nuclear reactor design fuel assembly

The TREAT core consists of a 19×19 array of 10-cm (4-in) square fuel assemblies arranged on a grid plate forming a 1.9-m (6-ft 4-in) square reactor core region. The fuel assemblies consist of a 1.2-m (4-ft) long fueled region with 0.6-m (2-ft) long graphite reflectors attached above and below (Fig. 3). The fueled region consists of 8 axially stacked graphite blocks containing a 0.3 wt% UO_2 powder (93% enriched) such that each assembly contains approximately 37.4 g U-235. The fueled segment is encapsulated in Zr-3 cladding. The graphite reflectors are similarly clad in aluminum and are attached to the fueled segment by rivets. The upper and lower heads of the fuel assembly are fitted with a handling fixture and a grid plate locating pin, respectively.

Pathways for the air coolant flow from the upper plenum to the lower plenum are formed within the reactor through slightly chamfered corners on the fuel assembly and a small standoff built into the end plugs. The chamfered corners create 16-mm (0.625-in) square coolant channels on the corners between fuel assemblies. The standoffs effectively separate the fuel surfaces between each fuel assembly by 2-mm (0.080-in.) and create additional cooling channels as well as protecting the fuel from damage during handling. Several of the fuel assemblies are also outfitted with thermo-couples to allow for core temperature monitoring during transients. The thermocouples are embedded in various internal locations including the cladding inner surface, fuel surface, and fuel centerline. These elements are strategically located in limiting temperature positions in the TREAT core to validate safety calculations associated with any given core configuration.

Nuclear physics parameters and reactivity control system

The TREAT facility is capable of generating peak thermal power approaching 2 GW during a limiting step reactivity insertion. At this power level the peak instantaneous neutron flux is greater than 10^{17} n/cm²/s¹. The flux nominally scales with the reactor power, depending on specifics of the experimental configuration, such that an instantaneous power of 10–50 MW (0.5–2.5% of peak power) can deliver fluxes prototypic of either an LWR or SFR, thus providing clear capacity to drive fuel up to and beyond the failure thresholds. However, these remarkable values do not adequately describe TREAT's critical nuclear physics parameters. The TREAT reactor is designed to deliver large shaped nuclear transients while leveraging its natural response to protect the plant from damage. This is accomplished through a fast acting, computer-controlled reactor control system that can introduce and remove reactivity based on a specific user's needs. This active control is backed up by a very strong negative reactivity feedback coefficient that ultimately terminates transients without control rod insertion. This behavior is a result of the unique thermal-nuclear response of the TREAT reactor (which is not the typical doppler shift seen in other reactors). During operation, the core is effectively adiabatic due to the high rate of power generation and the low rate of heat rejection. Significant negative reactivity is therefore inserted when the neutron energy spectrum shifts up toward higher energy as the graphite heats up, thereby reducing the effective fission cross section in the fuel phase. The reactor control system is therefore not relied upon for safety functions which provides the experimenter with remarkable flexibility in test design.

The TREAT reactivity control system consists of three independent types of control rods that are manipulated from the bottom of the core. The various drive systems push the control elements into the upper plenum such that downward movement, via gravity or control action, inserts negative reactivity into the core. The control elements consist of 4.45-cm (1.75-in) diameter B_4C rods clad in carbon steel. Each rod is 1.5-m (60-in) long and is followed by an upper and lower graphite extension clad in mild steel. Each rod penetrates the lower grid plate and is mated to special purpose fuel assemblies that have a central hole extending through its entire axial length that is designed to accommodate the rod and its movement.

The three types of TREAT reactor control rods, including (1) the compensation/shutdown rods, (2) control/shutdown rods, and (3) transient rods, each serve a specific reactor control function. The compensation/shutdown rods include four rods used to adjust the overall core reactivity worth when it is loaded with an experiment. The position of each rod is independently set prior to operation using a screw-driven drive mechanism. The rods are also used to terminate transients using a fast-acting, pneumatically accelerated scram system. The control/shutdown rods consist of eight rods assembled into two independent banks that are used to support reactor control during startup and steady state operations. These are operated by systems similar to the compensation/shutdown rods (e.g., screw driven control with pneumatic assisted scram). Finally, eight transient rods operated in four banks are used to initiate and control the reactor transient. The transient rods can be controlled either by an operator in "low-speed" mode or computer controlled in "high speed" mode. The transient rods are hydraulically driven at rates up to 3.56-m/s (140 in/s). The rods can be moved in either direction (in or out of the core) at this speed.

The reactor is typically operated in one of three modes, depending on the user needs, including steady state, temperature limited transient, or shaped transient. The reactor can be operated indefinitely in steady state mode at roughly 120 kW where the heat rejection and generation from the air cooling system and reactor core, respectively, are in balance. A temperature limited transient is induced through a step reactivity insertion achieved by rapid control rod ejection (Chase et al., 2019). During this event, the reactor power will exponentially increase until the negative reactivity insertion due to increasing core temperature is sufficient to fully suppress the power excursion. The size and length of the semi-Gaussian pulse shape will depend on the size of the specific reactivity insertion. The pulse width, typically characterized by its full-width at half-max, can range from 100s of milliseconds to several seconds when operated in this mode.

The most common TREAT operating mode is the shaped transient. In this mode the reactor control rod movements are pre-programmed into the automatic reactor control system in order to deliver the unique transient prescription required for a given experiment. A wide array of shaped transients can be executed with this system (Holschuh et al., 2019). The most common shaped transients are based on a series of simply segmented reactivity control actions. For example, a standard temperature limited transient

Fig. 3 Schematic of the TREAT fuel assembly (dimensions in inches).

can be “clipped” by early insertion of the control rods to terminate the transient and reduce pulse widths to below 80–90 ms (Bess et al., 2019). Addition of a He-3 based control “rod” operating in a similar mode is expected to shorten the pulse even further, perhaps as low as 40 ms. The reactor can also be operated at constant power greater than the steady state limit, known as a “flat top,” or at a fixed power ramp by gradually removing the control rods to make up for the core reactivity loss as the core heats up. While operating in this mode the reactor gradually heats up until reaching either the operating set point limits (2500 MJ of energy addition) or the excess reactivity is exhausted by the negative reactivity feedback changes that accompany core heating.

In more sophisticated shaped transients, multiple segments of these types can be combined to imitate complex events in nuclear reactors. This includes simulation of LWR loss of coolant accidents (LOCA) or SFR loss of flow (LOF) events that require a period of normal operation followed by a period of decay heat simulation. Shaped transients are typically only constrained to a maximum integrated TREAT core energy addition to limit core heating such that cladding temperatures do not exceed ~ 600 °C during normal operation or ~ 800 °C during accident conditions to prevent degradation of the Zry-3 cladding due to accelerated oxidation.

Core configuration

Within the core boundary, the fuel assemblies can be reconfigured within the constraints of the 19×19 grid plate to create test sections of various sizes (Fig. 4). The core is typically arranged to accommodate a 10-cm by 20-cm (4-in by 8-in) test section by removing two fuel assemblies. However, it can also be configured to accommodate up to a 25-cm (10-in) diameter test section (by removing 9 assemblies) that matches the core shield and the inner diameter of the experiment handling cask. This geometry is the effective mechanical constraint for experiment size. The experiment hardware, as discussed in a later section, is self-contained and readily inserted and removed from this test position.

Fig. 4 TREAT core layout including hodoscope slot, experiment position, and reactor control rod types and locations.

The TREAT core is surrounded successively by a 0.6-m (2-ft) permanent graphite reflector and 1.5-m (5-ft) concrete biological shielding region. Openings in both the biological shielding and reflector are available on each side of the reactor to create a direct line-of-sight to the core. These positions can be used to support specialized beamlines or for direct observation of the experiment. The West penetration is occupied by a neutron radiography station that is used to image experiments before and after irradiation (Jensen et al., 2019). The North penetration is occupied by the fuel motion monitoring system (also known as the fast neutron hodoscope) (Hix et al., 2017) which is used to monitor fuel motion in the test section during irradiation. This in-situ viewing is accomplished by creating an open channel between the experiment and the hodoscope detectors by removing a full row of fuel assemblies. Fast neutrons emitted from the test section propagate down this channel through a collimator and impinge on the hodoscope's detectors. These ZnS scintillators (Ocampo Giraldo et al., 2019) are sensitive to fast neutrons but are transparent to gamma radiation and thermal neutrons. Thus, the intensity of the fast neutron signal can then be correlated with the number of fissions occurring (and thus the fuel mass) in a particular region of the test section. While qualitative motion assessment is valuable and available for all experiments, advanced users can also achieve quantitative determination of the fuel mass through knowledge of both the local effective fission cross sections and reactor flux. The remaining two penetrations, on the South and East, remain available for special purpose applications.

Cooling system

TREAT's thermal management strategy is unique amongst the research reactor community in that, while the facility is characterized as air-cooled, during operation it is essentially adiabatic. TREAT's large, very dilute core (1:10,000 uranium to carbon atom ratio) provides a substantial thermal mass that absorbs virtually all of the fission heat generated during transient operation. Core temperatures commonly approach the operating limits of 600 °C during large transients while staying well below the safety limits of 820 °C where minor cladding damage can begin occur due to oxidation. The core heating is critical to providing the passive shutdown mechanisms described above. The heat is subsequently rejected over several hours through the air cooling system. This system nominally draws air from the reactor building into the upper plenum through two pre-filters on top of the reactor. However, the system is not leak tight and air can be drawn in from various openings in the core reflector and shielding. Air is then pulled into the core cooling channels and the lower plenum before being passed through a HEPA filtration system and exhausted through the building stack. This system is powered by two parallel blowers that are capable of driving 170 m³/min (6000 cfm) of air through the core. With full operation of the core cooling system, the core can be cooled and ready for additional transient operations in roughly 4 h.

The maximum threshold for total energy injected into the core during a transient is limited to 2500 MJ during a prompt pulse (<1 s) and 2900 MJ during a shaped transient to keep the cladding temperature below 600 °C. Below this temperature threshold there is virtual no oxidation of the Zry-3 cladding in air. If the temperature were to exceed roughly 800 °C, rapid oxidation would occur and lead to fuel damage. Although the fuel elements contain a negligible amount of radionuclide due to the extremely small amount of lifetime exposure associated with transient operations, fuel handling and continued use of the fuel for reactor operations could be problematic following exposure to temperatures greater than these thresholds.

Experiment systems

TREAT delivers a unique nuclear environment that can be representative of various transients of interest to a wide variety of nuclear systems. However, this must be complemented by experimental devices that deliver the desired thermal-hydraulic-mechanical environment required to meet the experiment objectives. These devices are entirely self-contained and operated independently from the TREAT driver core with their own control, instrumentation, and thermal management systems. A suite of experiment enabling devices has been developed (Woolstenhulme et al., 2019) to support cross-cutting missions that are tailored for a wide range of experimental objectives. These include integral tests that carefully match a projected accident scenario as well as simplified separate effects tests targeted at understanding general transient fuel behavior.

The simplest form of TREAT testing is conducted using a modular experimental system that separates components focused on reactor safety from components focused on experiment objectives (shown in Fig. 5). During the transient, the TREAT core must be protected from potential damage associated with postulated failures in the test hardware due to reactor or experiment design basis accidents. The broad use specimen transient experiment rig (BUSTER) module is built around a robust pressure vessel that meets these reactor safety function requirements. This pressure vessel takes the form of a long cylindrical 316-SS "pipe" with closure flanges that is mounted within a 10-cm by 20-cm (4-in by 8-in) package designed to interface with standard TREAT core structures and support routine handling (including transport to hot cell facilities if necessary). Insertion of the device is shown in Fig. 6. This device is reusable for multiple experiments and, thus, minimizes the repeating cost of experimental systems with significant safety implications.

The test hardware, called the sample environment rodlet transient testing apparatus (SERITA), is then inserted into the BUSTER pipe. This engineered system is loaded directly into the BUSTER pipe and is tailored to the unique experiment objectives by combining several experiment modules as necessary. The base unit for a SERITA device typically consist of a static capsule that is designed to contain a test sample and is equipped with several penetrations to support in-situ instrumentation (Jensen and Fleming, 2019). The separate effects tests holder (SETH) module represents the simplest capsule configuration available. This sealed capsule is produced through direct laser metal sintering (DLMS) of titanium alloy which allows for use of complex internal geometries defined by the experimenter. The capsule can be back filled with a user selected gas and offers limited environmental control

Fig. 5 The Multi-application reusable capsule holder system (including the BUSTER and SETH modules).

(e.g., electric pre-heat up to 700 °C prior to the nuclear transient). A variety of unique separate effects experiments can be accomplished using this test configuration; recent examples are described in [Woolstenhulme et al. \(2020a,b\)](#), [Schulthess et al. \(2020\)](#), [Spencer et al. \(2019\)](#), [Hernandez et al. \(2020\)](#), [O'Brien et al. \(2019\)](#), and [Brown \(2020\)](#).

A variety of additional modules can be added to the SETH-SERTTA device to enhance the range of experiment conditions available. For example, a pressurizer tank module was added to the top of the SETH capsule to allow for transient tests with the experiment submerged in pressurized water. This test configuration can be used to simulate the effects of both design basis accident and anticipated overpower events on light water reactor (LWR) fuels ([Kameraman, et al., 2020](#); [Emerson, et al., 2019](#)). Further, an expansion tank module with a fast acting relief valve can be attached to the bottom of this capsule to allow for its rapid, controlled depressurization. This test configuration can be used to simulate the early stages of an LWR loss of coolant accident (LOCA) ([Woolstenhulme et al., 2020a,b](#)). Following this methodology, modules have also been developed to support advanced reactor fuel testing applications.

Fig. 6 Photograph of the MARCH system being inserted into the TREAT reactor core.

More sophisticated experiment devices can also be deployed to conduct fully integral transient test simulations on engineering scale specimens. Self contained “cartridge”-style loops capable of recirculating flow with active control have been used extensively in TREAT to conduct both overpower and undercooling transient tests that simulate complex events ranging from anticipated operational occurrences through severe accidents. Loops to support both LWR (Woolstenhulme and Epiney, 2019) and sodium-cooled fast reactors (SFR) (Jensen et al., 2017) will be available for transient testing in the near future. These loop devices are prepared and loaded with pre-irradiated fuel at the INL’s hot fuel examination facility (HFEF) and are transferred to TREAT in a specialized transport container.

This model can be further extended beyond fuel system testing to support the study of integral reactor systems behavior. For example, TREAT’s unique design can also be leveraged to support investigation of integral micro-reactor systems. In this mode the TREAT core is configured to allow for incorporation of a large enough micro-reactor segment to capture all the key reactor systems. A dedicated heat rejection system is attached to provide prototypic cooling to the test section. The TREAT automatic reactor control system (ARCS) is programmed to respond to signals from the test segment (i.e., thermocouples embedded in the micro-reactor segment) with nuclear kinetics that mimic the full micro-reactor core. The integral system experiment can be driven by the TREAT core in either steady-state or transient mode to investigate dynamic response to a variety of events. These tests provide a significant incremental test bed that lies between benchtop demonstrations and prototype reactor facilities that can help accelerate both development and licensing of new designs.

Summary

The Transient Test Reactor (TREAT) at the Idaho National Laboratory is a special purpose test reactor designed to support transient testing of nuclear fuel and reactors components. These transients are primarily used to safely simulate the extreme environment inside a nuclear reactor core under off-normal or accident conditions. The versatility enabled by TREAT's unique design consisting of an air-cooled dispersed UO_2 fuel phase in a graphite pile and computer controlled, fast acting control rods is a foundational resource to nuclear reactor system developers. A variety of irradiation test devices and in-situ instruments can be inserted into TREAT's core to simulate the desired thermal-hydraulic conditions associated with virtually any reactor system during a user defined nuclear transient. This unique flexibility has allowed TREAT to support nuclear fuel development and testing activities for reactors ranging across standard light water reactors, research reactors, sodium cooled fast reactors, gas cooled reactors, and even space reactors.

Introduction

The Advanced Test Reactor (ATR) is an evolutionary research reactor that was conceived just over 16 years from the first criticality of Chicago Pile-1 (CP-1) and began operation less than 10 years later. The history and the evolution of ATR begins with the design, construction, and operation of the two high-flux test reactors that preceded it, the Materials Testing Reactor (MTR) and the Engineering Test Reactor (ETR) (Stacy, 2000). Lessons learned from the operation of those two earlier facilities were applied to the design of the ATR. All three test reactors were built and operated in one area, now called the ATR Complex, within what is now the Idaho National Laboratory (INL) site near Arco, Idaho. This INL area was originally a World War II naval ordnance proving ground and aerial bombing practice range. The US Atomic Energy Commission expanded the site and created the National Reactor Testing Station (NRTS) in 1949. The MTR planning began in 1947 but it was not clear where the reactor was to be constructed until the NRTS was created in Idaho and the AEC chose that location (due, in part to its remoteness) to build the MTR. Groundbreaking for the 30 MW MTR was in 1950 and the reactor went critical in March 1952. To achieve such a rapid construction schedule required the reactor facility to be designed almost at the same time as it was being built. The MTR was a highly-enriched-uranium fueled, beryllium-reflected and light-water cooled reactor. It was designed as a multipurpose reactor with over one hundred irradiation positions, including neutron beam tubes but was primarily focused on accelerated materials irradiation testing (Stacy, 2000).

For years, MTR was the highest neutron flux research reactor in the world, but scientists and engineers desired higher fluxes for testing and MTR power was raised to 40 MW in September 1955. However, it was already clear that even higher fluxes were required for some testing programs than MTR could provide so an improved test reactor design effort began in 1955. The Engineering Test Reactor would use fuel similar to the MTR, but the power level was raised to 175 MW which would increase the neutron flux above the MTR maximum by a factor of four or more. There were many design improvements in the ETR, but two significant changes allowed experimental loops in the reactor interior and moved the location of the control rod drive motors below the reactor. The MTR only permitted relatively small experiments to be irradiated and only on the periphery of the reactor core lattice. By 1955, larger samples, up to 10 in. in length, containing more fissionable materials required higher cooling and larger experimental volumes than MTR could provide. The ETR effective core height was 0.9 m versus the 0.6 m of the MTR core and the core lattice allowed approximately 7.6 cm by 7.6 cm locations for experiment insertion. Moving the control rod drives below the reactor allowed more access from above the reactor but still caused perturbations of the neutron flux as control rods were moved during operation (Gilbert and Stacy, 2006).

Phillips Petroleum Company was the first contractor company for the operation of the MTR and ETR and was asked in late 1959 to design an advanced engineering test reactor that would have a neutron flux in test positions greater than $1\text{E}15$ neutrons $\text{cm}^{-2} \text{ s}^{-1}$. The original conceptual design was referred to as ETR-II but the name eventually was changed to the Advanced Test Reactor (deBoisblanc et al., 1960).

The ATR is a unique purpose-specific reactor design and, with a maximum power of 250 MW, one of the highest power research reactors ever operated in the world. The building exterior of the ATR is shown below in Fig. 1. The ATR typically operates at lower powers, in the range of 115 MW, for normal experiments but does operate at higher power for specific experimenter needs. To achieve the high neutron flux, the fuel operates at high power densities of approximately 1 kW cm^{-3} . The ATR was designed to provide variable neutron flux in different experiment locations and achieves this by operating in a radially unbalanced power condition. The unbalance ratio may be as high as four to one across the core for specific experiment needs; however, this large of a power split is rarely used. As with many high power, high performance research reactors, the ATR core may contain all fresh fuel or

Fig. 1 External view of ATR building.

a mixture of fresh and recycled fuel elements to achieve experiment and cycle length demands. A typical experimental cycle for ATR is from 2 to 8 weeks but cycles as long as 9 weeks have occurred.

Originally conceived by Deslonde deBoisblanc, a senior Phillips Petroleum reactor physicist, the ATR is a very unusual design for a nuclear research reactor. Computer modeling of nuclear reactors was not advanced in the 1950s and the ATR physics parameters were initially calculated using two-group diffusion theory and with a two-dimensional computer code. Following the standard practice for the MTR and ETR facilities, a low power but physically identical version of the ATR core was constructed to validate these computational models and measure core physics characteristics prior to ATR's initial startup. This reactor was named the ATR Critical Facility (ATRC) and started up in 1964. The ATRC typically operates at 600 watts or less and is still used to benchmark computational models and measure reactivity effects of experiments prior to insertion into ATR. These tests are still required today, even with the available advanced computational modeling and simulation capabilities to assure safety is not compromised. As an aside, the ATR design was first mocked-up using the ETR Critical Facility (it had a rectangular grid array) to validate the conceptual five-lobe design and the computational approximations for a cylindrical flux trap.

Reactor internals

The ATR internals consist of a series of tanks or support structures internal to the reactor vessel. These tanks support the reactor fuel and reflector and direct primary coolant flow through the reactor core quadrants. The ATR operates with a pressurized primary cooling system (approximately 2.56 MPa) and uses demineralized light water for cooling. A significant portion of the cooling flow is directed downward through the fuel elements with the remainder providing cooling for the non-fuel reactor internals and experiments. At full flow the ATR primary coolant flow rate is $3.2 \text{ m}^3 \text{ s}^{-1}$. When three pumps are operating with approximately $2.2 \text{ m}^3 \text{ s}^{-1}$ flowing through the fuel.

Reactor fuel

The ATR reactor core contains 40 fuel elements arranged in a clover leaf or serpentine pattern that creates four lobe areas as shown in [Fig. 2](#) below. This geometry maximizes the neutron flux for cylindrical experiments located in the formed flux traps. ATR was originally designed to have nine experiment loops utilizing the flux traps but was reconfigured in 1994 to allow some flux trap locations to have experiments cooled by the reactor primary coolant. The ATR has been reconfigured several times to accommodate different experiments in the flux traps.

Each fuel element forms a 45-degree sector of a right circular cylinder and contains 19 fuel plates roll-swaged into the side plates. The side plates have machined vents that provide interconnection of flow channels from fuel element to fuel element and reduces pressure differentials. Each fuel plate contains an active fuel length of 1.22 m and is loaded with highly enriched uranium matrix (UAl_x) clad with 6061 aluminum alloy. Aluminum was selected due to its high thermal conductivity and low neutron cross section. The fuel elements are subjected to preconditioning at the manufacturer to establish a boehmite (a stable form of aluminum oxide) corrosion layer prior to use in the reactor for repeatable heat transfer. Small amounts of boron in the form of B_4C powder is added to some fuel plates as a burnable poison which allows longer cycle lengths and minimizes power peaking.

Fig. 2 ATR radial cross-section.

Reactivity control elements

The ATR reactivity control is unique in that it was designed to maintain a near cosine-shaped axial neutron flux profile throughout the operation cycle. The ATR has four independent reactivity control systems, and each has a separate function. These systems are the safety rod system, the neck (fine control) shim rod system, the regulating rod system, and the outer shim control cylinder (OSCC) system. The safety rod system consists of aluminum tubes with hafnium inserts and provides for the automatic or manual rapid shutdown capability. The safety rods are located in six of the nine flux traps areas and are nearly fully withdrawn (7.62 cm remain) above the core region prior to starting up the reactor. There are 24 neck shim and regulating rods located in the neck shim housing located in the center of the reactor. Two of the neck shim rods are used as regulating rods to maintain power automatically via a servo system. All neck shim rods are fully inserted at the beginning of a cycle and gradually pulled out throughout the cycle to compensate for local fuel burnup. The OSCC system consists of 16 beryllium cylinders and each cylinder is 1.19 m in length to be nearly the same height as the active fuel region. The cylinders each have a 120-degree hafnium insert and are operated in pairs to establish lobe power splits and compensate for fuel burnup. Lobe power splits refer to the ability of the ATR to adjust local lobe power for experiment specific power levels. Each lobe consists of the eight fuel elements surrounding a flux trap. ATR is currently potentially able to operate with up to a four to one ratio split across the core for certain experimental programs but generally operates with a 1–10-megawatt difference across the reactor.

Beryllium reflector

The ATR reflector is formed from eight high-grade beryllium manufactured pieces that fill the space between the fuel and the internal diameter wall of the core reflector tank. Primary coolant fills the area between the reflector tank and the reactor pressure vessel. Space is provided between beryllium segments and four holes are drilled through the beryllium sections for cooling water flow. Beryllium in a nuclear reactor will suffer irradiation damage that causes swelling and cracking. Horizontal saw cuts in the ATR beryllium reduce the tensile stresses and increases the reflector life by reducing crack lengths. Evaluation of reflector end of life is performed after stressed-induced cracking is first observed during routine examinations and consists of finite element stress analysis, more frequent inspections, and comparison to neutron fluence of previous reflectors. Approximately every 10–20 years, as determined by the swelling and cracking amount, the ATR beryllium is entirely replaced with new material. During this time, the majority of the other in-core components are also replaced in an evolution called a core internals change-out or CIC.

Instrumentation monitoring

ATR neutron power is monitored as with conventional research and power reactors by monitoring leakage neutrons which are proportional to total reactor power. These neutrons are detected by fission and neutron sensitive ion chambers in detector wells between the reactor reflector and the vessel wall. The ion and fission chambers are contained in 5-in. stainless steel instrument thimbles which are shown clearly in Fig. 3 below. Radiation streaming is minimized by installed shield plugs at the tube exit. Because the ATR typically operates in a power unbalanced condition with non-uniform power distribution, additional local power monitoring is required to monitor and control lobe power. Many neutron detector designs such as self-powered neutron detectors would quickly fail in the extreme neutron fluxes within the ATR. The ATR uses nitrogen-16 (N-16) and water power calculators to determine local lobe powers. The N-16 power monitoring system consists of 10 channels which use reentrant flow tubes in various core lobe regions to sample water flowing through these areas. Fast neutron flux, which is directly proportional to fission power, converts some oxygen in the water to N-16 with a 7.2 s half-life. The decay of the N-16 is detected using beta sensitive detectors and that signal is used to determine relative lobe power. Output from water power calculators and the N-16 power monitoring system are reduced by the reactor data acquisition system to yield the lobe powers.

Reactor vessel

Another unique feature of the ATR is that the reactor pressure vessel is entirely manufactured from 304 stainless steel. The vessel is 3.66 m in diameter, 10.7 m tall, and 50.8 mm thick at the core mid-plane. Stainless steel was selected, rather than clad carbon steel,

Fig. 3 Men standing on ATR during initial construction.

for corrosion resistance and a lower probability of brittle fracture after long radiation exposures. It is well known that the interaction of fast neutrons from the reactor with the stainless-steel increases tensile strength and reduces the ductility of the material. However, the fast neutron fluence on the ATR vessel is relatively low due to the intervening thicknesses of beryllium and reactor coolant which moderates and slows down fission neutrons as shown in Fig. 4. Calculated total fluence through the year 2060 only results in weldment fracture toughness reduced to 15% below the unirradiated materials; therefore, neutron embrittlement of the reactor vessel is not an issue in the foreseeable future for ATR.

Fresh fuel and new experiments may be loaded into the reactor vessel through penetrations in the reactor vessel head. Used fuel and experiments that are not in experiment loops are discharged to the working canal through a drop or discharge tube assembly. The penetration into the reactor vessel is closed during pressurized reactor operation using a double O-ring cover.

Reactor coolant enters the vessel through two 0.61-m pipes welded to the bottom vessel hemispherical head and then flows up through the area between the reactor core tanks (tanks are defined as enclosed areas, similar to pipes, that separate inlet and outlet coolant flows) and the vessel wall, including cooling the thermal shields. Thermal shields are used in higher power research reactors and nuclear power plants to minimize gamma radiation heating of the reactor pressure vessel. The reactor coolant then flows down through the core and into a flow-distribution tank which divides the flow into quadrants which then flow into four 0.41-m diameter outlet pipes which transport the coolant above the reactor core and out the four outlet nozzles. The coolant flow path then

Fig. 4 ATR vessel cut-away.

transitions to 0.46-m pipes which combine into two 0.61 m return lines and finally into a single 0.91-m line that distributes flow to the five primary to secondary coolant heat exchangers.

ATR primary cooling system pressure is maintained by a feed and bleed pressure control system. An automatic pressure control valve bleeds coolant through a degassing tank that removes dissolved gases from the coolant. A pressurizing pump draws coolant from the degassing tank and discharges through a flow control valve back to the primary cooling system. Rapid pressure changes are dampened by a surge tank which has a pressurized air and water volume to provide pressure control (Table 1).

Experiments locations and associated neutron fluxes

As seen in Fig. 2 above, the prime experimental locations in ATR are in the higher flux regions inside the serpentine fuel area, especially the nine-flux trap locations. There are 77 ATR experiment locations with B- and I-positions located outside the core periphery in the beryllium reflector. The position diameters vary from 1.59 to 12.7 cm, but all locations have a 1.22 m available height providing large experiment irradiation volumes. Table 2 summarizes the neutron flux levels in several ATR experiment locations. The peak flux values are given at 110 MW because the ATR rarely operates at full design power of 250 MW for an experiment cycle (ATR User Guide, 2008).

The ATR utilizes three basic in-core experiment configurations: static capsule, instrumented lead experiments, and pressurized water loops (ATR User Guide, 2008). Static or drop-in capsules are a more familiar type of irradiation experiment to users of other research reactors. A static capsule may contain small samples stacked within the welded volume or for large diameter locations (i.e. a flux trap or I-positions) there may be engineering scale components or materials within the capsule. Static capsules are cooled by the primary coolant system and temperature is controlled by a gas gap between the inner capsule and the outer capsule in contact with reactor coolant that is adjusted with pressures and gas mixtures to have a known thermal conductance. Further temperature control would be by selection of the core location to account for local power or gamma heating. No direct temperature monitoring is available for capsule experiments. Melt-wires may provide peak temperature indication and neutron-activated flux wires provide integrated neutron flux measurements when the sample capsule is opened.

Instrumented lead experiments allow control of some experiment parameters and real-time monitoring of the experiment conditions. These experiment capsules are not completely sealed and have small tubes leading in and out of the reactor vessel that carry instrument wires and control or monitoring gases. These experiments are more complicated than simple static capsules and require some type of monitoring and control station to automatically adjust parameters as needed. Temperatures of these experiments may be adjusted by varying the ratio of helium to neon gases in the gas gap to change the thermal conductivity of the gap or by adjusting local reactor powers if agreed to by other experimenters.

The final and most complicated experiment type used by the ATR is the pressurized water loop. These facilities are referred to as In-Pile Tubes (IPT) and are shown in Figs. 2, 3, and 5. These loops are designed to simulate the conditions (pressure, temperature, chemistry, etc.) of a pressurized water nuclear power reactor (PWR) within the low pressure, low temperature environment of the ATR. To achieve the PWR conditions, each loop experiment has a dedicated system that cools or heats the experiment and maintains high pressure conditions utilizing a scaled down pressurizer system. A low-pressure helium gas gap surrounds the pressure boundary in the reactor vessel to insulate the loop cooling system from the lower temperature ATR primary coolant. These experiments have significant real-time monitoring capability but are quite long (approximately 7.5 m) and must be removed from the

Table 1 ATR general characteristics.

<i>Reactor</i>	
Thermal power	250 MW _{th}
Power density	1.0 kW cm ⁻³

reactor by withdrawing the experiment into a shielded cask on the reactor top for discharge to the adjacent cooling and storage canal or packaged for shipment.

Additional information

In 2020, the ATR was one of the most utilized test reactors in the world with over 90% of the key test locations inside or near the reactor fuel scheduled for at least 5 years into the future. The ATR supports advanced reactor projects by irradiation materials testing of proposed liquid-metal cooled small modular reactors (SMR) materials and fuels, high-temperature gas-cooled reactor fuels (TRISO) (and structural graphite materials), and potential fuels for space propulsion systems. The ATR continues to provide irradiation testing of next generation LEU fuels that might replace the HEU fuels used in many high-performance research reactors and materials testing of advanced materials that could be used in current or future nuclear power plants. Finally, ATR

provides some radioisotope production capability for high specific activity materials and produces Pu-238 as a power source for deep-space probe missions.

Simulation of a fast spectrum reactor in a thermal reactor may be provided by inserting or designing a thermal neutron absorber around the experiment area to shield or filter the experiment neutron energy profile. Some common thermal neutron filters are boron, cadmium, and hafnium. The filters don't enhance the fast neutron spectrum but only remove the thermal energy neutrons. This may be done to test fast spectrum reactor fuels or to separate fast and thermal neutron damage effects for some materials. It is important for the experiment to be designed such that it is cooled by a non-thermalizing coolant, such as a gas or liquid metal to maximize the neutron energy interacting in the experiment. As was already noted, thermal neutron filters only remove low energy neutrons from the reactor energy spectrum and do not increase the numbers of fast neutrons at a given reactor power. Therefore, a thermal test reactor is not an ideal substitute for a fast spectrum test reactor which may have several orders of magnitude higher values of fast neutron fluxes. It is for this reason that countries considering building fast spectrum reactors will require a true fast spectrum test reactor capability. Russia is currently operating the BOR-60 fast spectrum test reactor and the US has begun a design and construction effort to build the Versatile Test Reactor (VTR).

Although the ATR has been operating for over 50 years, every operational cycle needs a different set of experiment conditions that must be established by variable power levels, nuclear material loading of the experiment, and length of the cycle. Because of this flexibility, every reactor core operated over the lifetime of ATR had to be re-designed completely to accommodate the particular experiments that were planned to be in the reactor. In the early several decades of operation, ATR was modeled using legacy computer codes with relatively little fidelity of the output. Today with the use of much more powerful computers, ATR is modeled in three-dimensions when it is necessary and in two-dimensions routinely to establish expected parameters and ensure they will be below safety limits.

Future of ATR

In 2016, the US Department of Energy began an investment program to replace or refurbish equipment at ATR that was operating beyond design lifetimes. This plant health program established long-term goals and plans to improve ATR operational reliability and provide a firm foundation to operate ATR for another two decades. The unique irradiation testing capabilities of the ATR are unlikely to be replaced in the near-term so this national and international asset will be maintained and upgraded as required to serve its diverse user community and provide essential long-term irradiation test program support well into the future.

Introduction

The High Flux Isotope Reactor (HFIR) is a versatile, multimission research reactor that is operated at Oak Ridge National Laboratory (ORNL) in Oak Ridge Tennessee, United States. With world-class capabilities, this US Department of Energy (DOE) Office of Science User Facility serves a variety of national missions and a broad range of science and technology communities. Neutrons produced in HFIR are used to support cold and thermal neutron scattering experiments, isotope production, materials irradiation research, and neutron activation analysis (NAA). Additionally, the gamma flux from used fuel cores is utilized for gamma irradiation studies, and neutrinos produced in the core are utilized for antineutrino studies. Fueled by 10.1 kg of highly enriched uranium (HEU) (9.4 kg ^{235}U) and operated at 85 MW_{th}, HFIR provides one of the highest steady-state neutron fluxes of any research reactor in the world.

Vision into reality

In October 1957, Glenn Seaborg, the co-discoverer of plutonium, californium, and other heavy elements (Rosenthal, 2010), wrote a letter to the Atomic Energy Commission (AEC) chairman that addressed the need for a new domestic very high-flux reactor capable of producing substantial, weighable quantities of heavy elements (e.g., berkelium, californium, einsteinium) to advance the field of transuranium element research. Seaborg was especially interested in the production of ^{252}Cf . A high-flux reactor is also advantageous in producing high specific activities of short-lived isotopes and accelerating the production of long-lived isotopes.

The Department of Energy will provide public access to these results of federally sponsored research in accordance with the DOE Public Access Plan (<http://energy.gov/downloads/doe-public-access-plan>).

A series of meetings were initiated in late 1957 to explore this need and to examine the technical problems of designing and constructing a new reactor capable of producing neutron fluxes an order of magnitude greater than any other domestic reactor at the time (Lane, 1958). In November 1958, it was recommended that a new high-flux reactor be designed, built, and operated at ORNL. ORNL concluded that an annular, HEU-fueled flux trap-type reactor consisting of a beryllium reflector, light water coolant, and a centrally located light water “island” (i.e., the flux trap) would provide the required thermal neutron fluxes. The HFIR core configuration is illustrated in Fig. 1. Construction was initiated in Melton Valley in 1961. HFIR was the thirteenth reactor to be built and operated at ORNL, and it is ORNL’s only remaining operating reactor.

Operational history

A series of fuel qualification irradiations and critical experiments were performed to qualify HFIR’s concept of a U_3O_8 -Al dispersion fuel and to finalize the design parameters of the fuel elements in the early 1960s. HFIR achieved criticality on August 25, 1965, and, following a low-power testing program, the reactor was brought to 100% design power (100 MW_{th}) in September 1966. The original operating inlet water coolant pressure of 4.24 MPa was raised to 5.27 MPa in 1977.

In November 1986, HFIR was temporarily shut down because tests on irradiation surveillance specimens indicated that the horizontal beam tube nozzle regions of the carbon steel vessel were being embrittled at a rate faster than predicted. As the result of embrittlement concerns, changes to accepted nuclear safety standards, and the incidents at Three Mile Island and Chernobyl, several committees were appointed to review various aspects of the reactor. In response, the power level was derated to 85 MW, and the operating pressure was reduced to 3.33 MPa. HFIR restarted in April 1989 for low-power operations and for training and achieved 85 MW in May 1990.

Facility evolution

The name of the reactor, High Flux Isotope Reactor, is expressive of its original isotope production mission; however, because of HFIR’s high-flux and spatially varying neutron energy distribution coupled with its easy accessibility for in-vessel experiments, it has evolved to become a multission neutron science research facility. The AEC expected HFIR’s sole mission would be heavy isotope production; however, Dr. Alvin Weinberg, the director of ORNL from 1955 to 1973, saw additional value in the inclusion of beam tubes emanating from the beryllium reflector that would allow neutrons to be beamed into experiments outside the reactor shielding. HFIR’s primary mission today is to conduct neutron scattering research, which is enabled because of Dr. Weinberg’s forethought to incorporate beam tubes into the design. Today, HFIR’s missions include cold neutron scattering, thermal neutron scattering, radioisotope production, materials irradiation, NAA, gamma irradiation, and fundamental physics research. Fig. 2 illustrates the versatile in-core experiment layout.

Fig. 1 High Flux Isotope Reactor core mockup.

Fig. 2 In-core experiment facility layout.

The first pneumatic tube was installed in 1970 to enable NAA capabilities; in 1987, the second pneumatic tube was installed to further enhance its world-class NAA capabilities. The number and size of material irradiation facilities were expanded in 1987 to improve the efficiency and throughput for materials irradiation research. In 2000, horizontal beam tube number 2 (HB-2) was replaced with a larger beam tube, which resulted in a threefold increase in thermal neutron flux. Horizontal beam tube number 4 (HB-4) was converted into a powerful liquid hydrogen cold neutron source beamline in 2007, resulting in a continuous high-brightness source of cold neutrons being delivered to the cold guide hall instruments. In preparation for the ~2024 permanent beryllium reflector replacement outage, the permanent reflector was redesigned to increase the number of irradiation facilities from 22 to 28, enhance irradiation experiment versatility, and improve thermal-structural performance ([Chandler et al., 2019](#)).

HFIR nuclear reactor design

Nuclear design, experiment, and analysis activities were performed to determine the HFIR core design. The reactor operates at 100% nominal 85 MW_{th} power for ~23–26 day fuel cycles. Currently, HFIR operates seven cycles per year. Both the inner and outer fuel elements are replaced during the end-of-cycle outages, which typically vary between about 2 and 7 weeks. Extended outages are required for some activities, such as replacing the permanent beryllium reflector and making significant updates to the horizontal beam tubes.

Reactor core assembly

The HFIR reactor core assembly design consists of a series of concentric regions about 61 cm in height, including, from the core centerline outward, a flux trap target region, an inner fuel element (IFE), an outer fuel element (OFE), a control element region, and a beryllium reflector ([Fig. 1](#)). The core is axially and radially reflected by light water and is contained in a pressure vessel, which itself is in a pool of light water.

Flux trap

The flux trap, which is located in the centermost region of the core, is 12.70 cm in diameter and utilizes a basket-type design to provide 37 target positions: 31 inside the basket assembly and 6 positions around the periphery of the basket, close to the IFE. The peripheral target positions are typically occupied by materials irradiation experiments that require high fast neutron fluxes. The interior flux trap positions are occupied by capsules containing materials for isotope production and materials irradiation experiments. Experiments requiring high thermal neutron fluxes are often placed near the center of the flux trap.

A hydraulic tube facility allows for up to nine small irradiation capsules (called “rabbits”) to be transported to and from the core on demand using the pressure drop in the core. The hydraulic tube consists of the necessary piping, valving, and instrumentation to move capsules during reactor operation, which enables short to full cycle irradiation periods. The hydraulic tube is especially advantageous for isotopes that reach an equilibrium concentration sooner than the nominal HFIR cycle length.

Fuel elements

The HFIR fuel assembly consists of an integral two-element configuration composed of two concentric fuel annuli. The IFE and OFE contain 171 and 369 fuel plates, respectively, and each of the 540 involute-shaped plates contain fuel meat in the form of U_3O_8 -Al cermet encapsulated in aluminum-6061 clad (Fig. 1). The fuel plate design incorporates a dispersion core with fuel particles dispersed in a continuous aluminum matrix metallurgically bonded to the aluminum alloy cladding. The involute shape is advantageous for several reasons: it provides a uniform metal-to-water ratio with a constant coolant gap thickness, it allows for circular fuel elements with only one unique plate per element, it provides a means for varying the fuel concentration in the radial direction, it minimizes mechanical instability issues (e.g., buckling), it provides a high ratio of heat transfer surface area to fuel region volume, and it maintains azimuthal symmetry and adequate coolant channel thickness when considering channel narrowing effects such as thermal expansion (Cheverton and Sims, 1971).

The fuel is HEU enriched to ~ 93 wt% ^{235}U and ~ 2.6 and 6.8 kg of ^{235}U are loaded into the IFE and OFE, respectively (9.4 kg total). The fuel is contoured along the arc of the involute (i.e., nonuniformly distributed), with thinner fuel at the lateral ends to reduce edge power peaking. The IFE’s aluminum filler region, which is adjacent to the fuel meat, contains B_4C burnable poison for reactivity hold-down and edge power suppression purposes. The lateral edges of the fuel meat directly face water and beryllium moderators/reflectors (e.g., flux trap, labyrinth between elements, and beryllium reflector), which cause thermal flux and power density peaks at the edges. Thin fuel edges and burnable poisons suppress the edge power thereby flattening the power profile and increasing the thermal safety margin.

For both plate types, the fuel plus filler region thickness is 0.762 mm, and the clad thickness is 0.254 mm. The fuel plates are thus 1.27 mm thick and, because of their involute shape, adjacent fuel plates are separated by a constant 1.27 mm coolant channel width (metal-to-water ratio of 1). Each fuel plate is 60.96 cm in length, and the active fuel zone length is 50.80 cm. The fuel plates are inserted into cylindrical side plates and are attached via welds. The IFE has inside and outside diameters of 12.88 and 26.87 cm, respectively; the OFE has inside and outside diameters of 28.54 and 43.53 cm, respectively. The active volume of the core is ~ 50 L, and thus the average power density is ~ 1.7 MW/L.

Control elements

Two concentric control elements, in the form of thin (0.635 cm thick) neutron poison-bearing cylinders, are located in the annular region between the OFE and the beryllium reflector. The inner control element consists of four curved control plates welded together to form a cylinder, which is used for shimming and power regulation purposes. Four individual shim-safety plates (i.e., quadrants), each having an independent drive and safety release mechanism, form the outer control element, which is used for both power regulation and safety purposes.

Each aluminum-cladded control plate consists of three distinct longitudinal core regions with various neutron absorption capabilities. The white regions located at the upper and lower extremes of the plates are made of aluminum, which is essentially transparent to neutrons. A 12.70 cm long gray region consisting of tantalum-aluminum has a moderate neutron absorption cross section and is used for fine power regulation. The 55.88 cm long black region contains Eu_2O_3 -Al, which is a strong neutron absorber and is used for power regulation and fast scram purposes.

Beryllium reflector

A large beryllium reflector (~ 30.49 cm thick), as shown in Fig. 1, provides very efficient neutron moderation and reflection properties. To accommodate the replacement frequency associated with radiation damage, the reflector is subdivided into three regions to allow the innermost regions to be more easily replaceable. These three regions, in order of their distance from the core centerline and their operational lifetime, are the removable beryllium reflector (RB), the semi-permanent beryllium reflector (SPB), and the permanent beryllium reflector (PB). The reflector experiment facilities can accommodate static experimental capsules, complex-testing engineering loops, and special experimental isotope irradiations.

The RB has eight large aluminum-lined RB experiment facilities and four small unlined RB facilities. The large RB facilities can be used for instrumented or uninstrumented experiments. The SPB contains four control rod access plugs, each providing two small unlined irradiation facilities. The PB, which is the largest of the three reflector regions, is a single large annulus of beryllium penetrated by 22 vertical experiment facilities (VXF), four horizontal beam tubes, and two engineering slant facility tubes. One VXF facility and one engineering slant facility each contain a pneumatic tube facility that uses differential pneumatic air pressure to shuttle small capsules from shielded work areas to the reactor and back for NAA. Four horizontal beam tubes penetrate the reflector and terminate at instruments in the beam room and cold guide hall, where thermal neutron scattering and cold neutron scattering are performed, respectively.

Pressure vessel

The reactor pressure vessel cylinder (i.e., shell) has an inner diameter of about 2.39 m and is constructed of carbon steel clad with austenitic stainless steel on both sides. A stainless steel extension is attached to the lower end of the vessel to permit control

element access to the core through the 2.14 m thick pool floor. The flat lower head is nominally 15.24 cm thick. The upper vessel head is made of 35.56 cm thick carbon steel clad with stainless steel and is secured to the vessel with bolts and sealed with an O-ring (SAR, 2019). Illustrations of the pressure vessel and the flow distribution within it are provided in Fig. 3.

A quick-opening access hatch with a diameter of 76.20 cm is located in the center of the upper head to enable movement of fuel elements, targets, control elements, and inner reflector pieces without the upper head being removed. The openings (i.e., nozzles) where the four horizontal beam tubes penetrate the vessel are exposed to higher radiation damage rates than the other regions of the vessel because of the ability of radiation to stream down the beamlines with limited shielding. With an expected lifetime of ~ 50 effective full power years at 100 MW, the vessel will need to be replaced in the 2050–70 timeframe, depending on future operating schedules. If a future vessel replacement occurs, it will likely be of a similar design, but employ stainless steel to avoid future embrittlement issues.

Nuclear physics overview

Highly energetic neutrons are created from fission reactions in the fuel and are subsequently slowed down via interactions with materials such as the water moderator and the beryllium reflector. At the beginning of cycle (BOC), the peak IFE and OFE fission rate densities are $\sim 6.9 \times 10^{14}$ and 6.0×10^{14} fissions- $\text{cm}^{-3} \text{ s}^{-1}$ and occur on the core midplane at the inner and outer radius of the elements, respectively (Chandler et al., 2019). As the fuel depletes over the course of the cycle, the power distribution flattens, and the peak IFE and OFE fission rate densities decrease to $\sim 3.2 \times 10^{14}$ and 4.7×10^{14} fissions- $\text{cm}^{-3} \text{ s}^{-1}$, respectively, at the end of cycle (EOC).

The unirradiated HFIR fuel assembly contains ~ 10.1 kg total uranium and therefore reaches an average burnup of about 220 MWd/kg U during a 2200 MWd operating cycle. At a recoverable energy of 200 MeV per fission, this is equivalent to about 0.23 fissions per initial uranium atom. The peak EOC cumulative fission density for the IFE and OFE are $\sim 1.1 \times 10^{21}$ and 1.3×10^{21} fissions- cm^{-3} , respectively (Chandler et al., 2020). Both peaks occur on the core horizontal midplane; the IFE peak occurs at the inner radial edge adjacent to the flux trap; the OFE peak occurs at the outer radial edge adjacent to the beryllium reflector.

Fig. 4 illustrates the core midplane BOC and EOC radially dependent three-energy group neutron flux profiles with thermal, epithermal, and fast neutron energy boundaries of 0.625 eV, 0.1, and 20 MeV, respectively. The peak fast neutron flux of $\sim 2.0 \times 10^{15}$ neutrons- $\text{cm}^{-2} \text{ s}^{-1}$ occurs in the IFE. Neutrons that leak into the flux trap slow down via interactions with water, which is why the thermal neutron flux increases from $\sim 1.5 \times 10^{15}$ to 2.5×10^{15} neutrons- $\text{cm}^{-2} \text{ s}^{-1}$ from the outer radius of the flux trap to the centerline of the flux trap and the fast neutron flux decreases from $\sim 1.5 \times 10^{15}$ to 1.0×10^{15} neutrons- $\text{cm}^{-2} \text{ s}^{-1}$. Similarly, as neutrons leak out into the beryllium reflector, their energy is reduced due to interactions with the beryllium. At BOC and EOC, the peak thermal neutron flux in the beryllium reflector is about 1.1×10^{15} and 1.4×10^{15} neutrons- $\text{cm}^{-2} \text{ s}^{-1}$, respectively.

The spectral brightness of the HB-4 cold source operating with a liquid hydrogen moderator temperature of 22.5 K and a reactor power level of 85 MW is described in (Robertson and Iverson, 2008). The peak brightness of $\sim 1\text{--}2 \times 10^{13}$ neutrons- $\text{cm}^{-2} \text{ s}^{-1} \text{ str}^{-1} \text{ \AA}^{-1}$ occurs in the 2–3 Å energy range.

Fig. 3 Reactor pressure vessel and flow distribution.

Fig. 4 Radial three energy group neutron flux profiles.

Reactivity control and safety systems

The fuel assembly cannot achieve criticality without being contained within the beryllium reflector. Therefore, the control elements are in the annulus between the fuel and the reflector to vary the efficiency of the reflector. The control element drive mechanisms, located in the subpile room below the pressure vessel, drive the control elements in the axial direction. When the reactor is shut down, the europium-bearing black regions of the control elements are adjacent to the active fuel zones. However, during operation, the elements are symmetrically withdrawn in opposite directions with the shim-safety plates being withdrawn vertically upwards and the shim-regulating cylinder being withdrawn downwards. The symmetric movement drives the poison-bearing regions away from the core midplane, increases the “neutron window,” maintains criticality, and maintains axial symmetry in the power distribution. The reactor achieves criticality when a small window opens about the core midplane. The control elements continue to withdraw throughout the cycle to compensate for fuel depletion and fission product buildup.

A servo-control system maintains constant power by moving the inner shim-regulating cylinder, which is accomplished through a system of three independent servo channels, each supplied with a servo reset flux signal. Each servo channel compares the operating power level indicated by the reset flux signal with the requested power indicated by its servo demand setting (SAR, 2019). The neutron flux level is monitored by six ionization chambers (three associated with the servo-regulating system and three associated with the safety system) located in three thimbles that are positioned around the periphery of the beryllium reflector, each containing one servo and one safety ion chamber.

The reactor instrumentation and control system design reflects the emphasis placed on the importance of continuity of operation while maintaining safe operation. It is an independent protection system whose function is to monitor reactor conditions and provide a method of initiating a rapid shutdown should any of the parameters affecting safety exceed preset values. Three independent safety channels are arranged in a coincidence system that requires agreement of two of the three for reactor shutdown. The shim-safety plates and drives are designed to ensure that the reactor can be reliably shut down whenever a protection system parameter reaches its trip threshold. Any single shim-safety plate or the shim-regulating cylinder can shut down the reactor or maintain the reactor subcritical under clean conditions with the other plates fully withdrawn. The shim-safety plates travel from fully withdrawn to fully inserted within ~ 250 ms.

Primary and secondary cooling systems

The primary coolant system’s key safety functions include heat removal, pressure boundary integrity of the high-pressure system, reactor vessel overcooling protection, containment of fission products, prevention of coolant flow blockage through the core, and maintenance of core exit pressure. Down-flowing demineralized water coolant enters the pressure vessel through two inlets above the reactor, passes through the core, and then exits the vessel through the outlet below the core. The inlet coolant temperature and pressure are ~ 48.89 °C and 3.33 MPa, respectively. Approximately $0.82 \text{ m}^3 \text{ s}^{-1}$ of the total $1.01 \text{ m}^3 \text{ s}^{-1}$ coolant flow passes through the fuel elements where a ΔT and ΔP of ~ 20 °C and 0.76 MPa, respectively, are nominally maintained. These conditions result in a coolant velocity of $\sim 15.54 \text{ m s}^{-1}$ through the fuel elements.

The flow passes through the target, fuel, control, and reflector regions in parallel paths, and, after exiting the pressure vessel, the coolant branches into four parallel headers. The coolant flow is typically distributed to three of four identical shell and U-tube-type heat exchanger and single-speed vertical centrifugal primary circulation pump combinations. The primary water from each heat

exchanger enters the associated main circulating pump and then recombines in a return line before passing through the inlet strainer and entering the reactor vessel. The primary coolant passes through the tube side of the heat exchangers, where the primary coolant gives up its heat to the secondary coolant, which is circulated through the shell side of the heat exchangers. The heat in the secondary coolant is dissipated to the atmosphere via a four-cell conventional induced-draft cooling tower mounted over a concrete basin.

Decay heat removal following reactor shutdown is normally provided by continuing to operate the primary coolant pumps to reject heat to the secondary; however, if the primary pumps aren't available, decay heat is removed by circulating the primary coolant via the dc-powered pony motor pumps.

Containment system

HFIR containment is defined as the primary coolant system pressure boundary as it is employed to contain fission products (SAR, 2019). A dynamic containment design, referred to as a confinement system, is employed. The system maintains a constant negative internal pressure with respect to atmosphere. Controlled ventilation moves air from areas of less potential contamination to areas of high potential contamination. Establishing and maintaining a controlled in-leakage within the confinement safety-related boundary are accomplished by the special building hot exhaust (SBHE) system, which establishes a negative pressure within the physical boundary envelope. Air exhausted by the SBHE system is routed from intake headers in the reactor bay to an underground filter pit. After passing through the filters, exhausted air is monitored and discharged up the exhaust stack, and any residual activity (i.e., noble gases, filter penetration) is dispersed by diffusion.

Current path to conversion to low-enriched uranium fuel

In collaboration with the US Reactor Conversion Program, ORNL has been performing engineering evaluations on the conversion of HFIR from HEU to low-enriched uranium (LEU) fuel since 2005. ORNL is funded by the US DOE National Nuclear Security Administration's Office of Material Management and Minimization to perform conversion studies as part of its nuclear nonproliferation mission. HFIR is committed to converting to LEU once a fuel form capable of ensuring that operations will continue at the current functional and scientific performance level in a safe, reliable, and affordable manner.

HFIR LEU conversion is planned to take place in five phases with the appropriate safety basis preparation by ORNL and with the approval for each by the US DOE Office of Science. The first phase is to present the US DOE Office of Science with a Preliminary Documented Safety Analysis. The second phase consists of running at least one cycle with the current HEU fuel at the higher power required for LEU conversion (e.g., 95 MW) to demonstrate the ability of the reactor cooling systems to remove the higher heat load. In the third phase, in-vessel, zero- and low-power tests of the LEU lead test core (LTC) will be conducted to confirm calculated neutronic parameters. Then, a single cycle with the LTC will be run at the higher power to demonstrate the continued ability to perform HFIR's scientific mission safely. The fifth and final phase consists of operating HFIR long term with LEU fuel at the higher power. The current HFIR conversion date is November 2033 (NNSA, 2019).

Fuel design studies have been conducted by ORNL to evaluate performance and safety metrics for two proposed fuel systems: uranium-molybdenum monolithic alloy (U-10Mo) and uranium-silicide dispersion (U_3Si_2 -Al). Results to date indicate that HFIR could convert to LEU fuel and maintain both performance and safety with the U-10Mo or U_3Si_2 -Al dispersion fuel systems if, among other considerations, the reactor power is increased, fabrication of the specific design features are successfully demonstrated, and the fuel forms are qualified for HFIR-specific irradiation conditions.

Experiment capabilities and highlights

ORNL maintains the missions of high-impact research about the structure and properties of materials across the spectrum of biology, chemistry, physics, materials science, and engineering as well as isotope production, neutron and gamma-induced damage testing of materials, and NAA. Neutrino and other fundamental physics research experiments are also performed at HFIR.

Cold and thermal neutron scattering

Neutrons are generated from fission reactions in HFIR's fuel at very high energies and are subsequently slowed down as they traverse through and interact with the water coolant/moderator, beryllium reflector, and cold source liquid hydrogen moderator. The low-energy neutrons that are directed down the horizontal beam tubes travel to instruments at the end of the beamlines, which allow users to study the structures and dynamics of materials. Originally, all four horizontal beam tubes (HB-1, HB-2, HB-3, and HB-4) delivered thermal neutrons to the thermal beam room; however, in 2007, HB-4 was converted into a powerful cold neutron source and has since been producing the brightest continuous source of cold neutrons in the world. A liquid hydrogen cold source moderator was installed in HB-4, and a new cold neutron guide hall was built to support cold neutron scattering. The layout of the four beam tubes is illustrated in Fig. 5.

Currently, there are seven instrument stations in the thermal beam room and five instruments at the end of the cold source beam tube that are operational and available in the user program. Additionally, there are currently three cold instruments and one thermal instrument in commissioning or operating as development beamlines. The intense neutron flux is used by more than 500

Fig. 5 Horizontal beam tube layout.

researchers each year for neutron scattering research. The neutron scattering research facilities contain a world-class collection of instruments used for fundamental and applied research (HFIR, 2020).

The HB-1 and HB-3 beam tubes are situated tangential to the core while HB-2, the largest of the four beam tubes, extends radially outward from the core centerline such that it directly faces the fuel elements. These thermal beam tubes terminate in the beam room where the thermal neutron instrument suite, consisting principally of triple-axis spectrometers (e.g., fixed-incident-energy, polarized), diffractometers (e.g., four-circle, neutron powder, wide-angle), and a residual stress mapping facility, resides. Versatile sample environments allow for measurements under extreme conditions (e.g., temperature, pressure, magnetic field). Thermal neutrons are used for research focused on impactful scientific discovery across many disciplines, such as studies of magnetic structures, high-temperature superconductors, thermoelectrics, potential quantum spin liquid materials, powdered and ceramic materials, diffuse scattering in single crystals, static and dynamic properties of spin and lattice, and residual stresses in materials.

The HB-4 tangential beam tube has an aluminum moderator vessel that contains supercritical hydrogen that is nominally maintained at 17 K. Thermal neutrons from the reflector scatter into the moderator vessel, where they are further moderated to cold energy levels (i.e., wavelengths of $\sim 4\text{--}12$ Å). The stream of neutrons delivered down HB-4 is split into four individual beams, each of which is directed down a cold guide that terminates in the cold guide hall. The cold neutron instrument suite principally includes instruments for imaging, small-angle neutron scattering, triple-axis spectrometer, and diffractometer studies. The imaging beamline is used for neutron radiography and computed tomography for applications in additive manufacturing, materials science, geoscience, biology, energy, and transportation. The general purpose and biological small-angle instruments are vastly used for soft condensed matter, hard condensed matter, magnetic systems, bio-macromolecules, bio-membranes, complex systems, biomass, biofuels, and biomaterials studies. A triple-axis spectrometer is ideal to study static and dynamic properties of spin and lattice in materials. The neutron image plate, single-crystal diffractometer provides atomic-resolution information on structures in biology, chemistry, and complex materials.

Isotope production

The in-core experiment facilities, as illustrated in Fig. 2 and previously discussed in the Flux Trap and Beryllium Reflector sections, are used for medical, industrial, and research isotope production. The ^{244}Cm , ^{248}Cm , ^{249}Bk , ^{249}Cf , ^{252}Cf , and ^{254}Es isotopes are the most commonly produced heavy isotopes at HFIR, are chemically separated at ORNL's Radioisotope Engineering Development Center (REDC), and are utilized for heavy element research. The isotopes are produced by irradiating aluminum-cladded targets containing a stack of curium oxide pellets with a stack height of about 50 cm and a composition typically consisting of a mixture of plutonium, americium, and curium isotopes as feed material.

About 80% of the world's supply of ^{252}Cf is produced at HFIR (Roberto, 2019). The ^{252}Cf isotope has a half-life of 2.645 years and decays via alpha emission and spontaneous fission (3.09% of the decays are through spontaneous fission). With a high neutron emission rate of $\sim 2.3 \times 10^6$ neutrons $\cdot\text{s}^{-1}\cdot\mu\text{g}^{-1}$, ^{252}Cf is used for a variety of unique purposes, such as treating certain types of brain

and cervical cancers, detecting metal fatigue in aircraft, and university education. In the nuclear industry, it is used to determine fuel enrichment and as a reactor startup source. For national security purposes, it is used to inspect shipping containers and to calibrate detectors. It is also used for prompt gamma neutron activation analysis in the cement, coal, mineral, and power plant industries for process control.

Isotopes produced in HFIR via neutron transmutations have been utilized in research that has led to element and isotope discoveries. Recently, as part of a US-Russian collaborative effort, ^{249}Bk produced in HFIR and isolated by REDC was sent to Russia, where it was bombarded by a calcium ion beam to form element 117. This element was named tennessine because of the efforts from both ORNL and Vanderbilt University, both of which reside in the state of Tennessee. In addition to element 117, ORNL-produced materials and isotopes have been used in the discoveries of superheavy elements 104 (rutherfordium), 105 (dubnium), 106 (seaborgium), 114 (flerovium), 115 (moscovium), 116 (livermorium), and 118 (oganesson). Ongoing research is being performed with ^{248}Cm , which upon bombardment with a vanadium beam, will produce element 119, if successful.

The ^{63}Ni and ^{75}Se isotopes, in high specific activities, are routinely produced in HFIR's flux trap. The ^{63}Ni isotope is used in electron capture technology for national security applications such as detection of explosives and drugs in airports. The ^{75}Se isotope is used for commercial and industrial gamma radiography (e.g., nondestructive testing applications such as pipeline weld inspections). The ^{133}Ba isotope is also produced at HFIR because it is an ideal isotope for calibration of instruments used in the oil and gas industries.

Radioisotope production is also very important for the medical industry for use in treating conditions such as cancer, arthritis, bone metastases, and restenosis. Other US-based research reactors, such as the Missouri University Research Reactor, produce medical radioisotopes; however, HFIR produces high specific activity radioisotopes that cannot be efficiently produced in other reactors. The medical radioisotopes produced at HFIR include ^{14}C , ^{89}Sr , ^{166}Ho , ^{177}Lu , ^{188}W , ^{227}Ac , and ^{229}Th . Additional isotopes are being considered as the medical field surrounding targeted alpha and beta therapies matures. Furthermore, ^{99}Mo research and development relies on HFIR to support aspiring domestic producers to develop their production technologies, to support medical diagnostics and treatments that utilize this radioisotope.

The production of ^{238}Pu takes place in HFIR's beryllium reflector VXF's via irradiation of ^{237}Np in the form of $\text{NpO}_2\text{-Al}$ cermet or NpO_2 oxide pellets contained in target assemblies. Loaded with PuO_2 fuel, radioisotope thermoelectric generators (RTG) convert heat energy produced from the alpha decay of ^{238}Pu (half-life of 87.7 years) into useable electricity and are used as a reliable power source for deep space and planetary National Aeronautics and Space Administration (NASA) missions. An RTG provided electrical power for NASA's Cassini spacecraft and is used to charge the batteries that power the Mars Perseverance and Curiosity rovers and their instruments.

Materials irradiation

The in-core experiment facilities are also used for research on severe neutron and gamma damage to materials. Because of its very high neutron flux environment, HFIR can simulate the full life of radiation exposure for commercial, fission-based reactor materials and components in a reasonable timeframe. HFIR is typically loaded with more than 100 separate experiment capsules and thousands of test specimens of various materials for research of future reactor materials as well as life extensions of current power reactor fleets. Data obtained from the irradiations are used for the qualification of new reactor component materials, including fuel cladding and reactor vessel materials. The HFIR materials irradiation mission also supports fusion energy development. Specifically, areas including neutron interactive materials (structural materials and ceramics), high-heat flux materials, and plasma-interactive materials are supported.

The materials research is enabled by HFIR's ability to accelerate damage testing using the highest fast neutron flux in the Western world, producing up to 2 displacements per atom (dpa) in steel during a single HFIR operating cycle of ~ 25 days. Additionally, a unique irradiation facility allows experimenters to actively monitor and control temperatures inside experiment capsules during irradiation via resistance heaters, variation in sweep gas compositions, and thermocouple measurements.

Neutron activation analysis

Two pneumatic tube facilities are available in the beryllium reflector as illustrated in Fig. 2. Each facility consists of a flight tube, air supply and exhaust lines, a loading station in the NAA laboratory, and irradiation stations. NAA offers a combination of ultrasensitive measurements and fast turnaround for determining the presence of certain isotopes/elements in materials. The facilities offer thermal neutron fluxes of up to about 4×10^{14} neutrons $\cdot\text{cm}^{-2}\cdot\text{s}^{-1}$. Additionally, the neutron spectra in these facilities are very soft (i.e., high thermal-to-total flux ratio). The NAA lab provides irradiation and detection services for a wide variety of programs, including nuclear forensics and criminal forensics. Some of the major applications include research of material impurities, detection of trace quantities of nuclear materials, understanding the nature and quantity of pollution in the environment, and qualifying ultrapure materials used in highly sensitive detectors.

Gamma irradiation

The Gamma Irradiation Facility employs used fuel elements to irradiate experiments with high doses of gamma radiation to study the effects of radiation on materials. With the flexibility to select fuel elements based on their decay time, users can obtain dose rates up to 1.8×10^8 rad $\cdot\text{h}^{-1}$ with used-fuel gamma spectra for rapid materials testing. The facility has been used for a variety of

applications, from testing materials for a nuclear reactor on the moon to research of radiation effects on artificial spinal disc materials. Gamma irradiation research has been used to test the effects of gamma dose on selected resins that are being evaluated for removing ^{137}Cs from high-level waste solutions. The facility has also been used for investigating radiation resistance of circuit boards for lunar reactor environments for NASA, determining radiation-induced changes in the conductivity of high-voltage insulators, and evaluating new radiation-resistant concrete formulations for nuclear power applications.

Fundamental physics

Fundamental physics research is ongoing at HFIR in support of its multimission objective. One example is the Precision Reactor Oscillation and SPECTrum Experiment (PROSPECT), which is a short-baseline reactor antineutrino experiment with the goals of discovering eV-scale neutrinos through oscillation effect observations, testing reactor antineutrino spectrum predictions, demonstrating antineutrino detection techniques, and developing technology for nonproliferation applications (Ashenfelter et al., 2019). HFIR is an ideal test bed for this type of experiment because it has a high-power-density, well-understood compact core with a ^{235}U fission fraction greater than 0.99 throughout the entire fuel cycle.

Conclusion

As a US DOE Office of Science User Facility, the HFIR, located in Oak Ridge, Tennessee, provides world-class neutron science capabilities to serve a variety of science and technology communities. HFIR is a pressurized, light-water-cooled, and beryllium-reflected research reactor that has a unique flux trap-type design. The central flux trap basket is surrounded by a cylindrical fuel assembly consisting of two concentric fuel elements that collectively bear 540 involute-shaped fuel plates. Fueled by 9.4 kg ^{235}U and operated at 85 MW, HFIR provides one of the highest steady-state neutron fluxes of any research reactor in the world. The peak, unperturbed thermal and fast neutron fluxes available in the flux trap are $\sim 2.5 \times 10^{15}$ and 1.4×10^{15} neutrons-cm $^{-2}$ -s $^{-1}$, respectively. The high-power density core, intense neutron flux, and versatile experiment configuration enable world-leading science in mission areas such as cold and thermal neutron scattering, radioisotope production, materials irradiation research, and neutron activation analysis.

HFIR was designed principally to produce heavy isotopes at the highest possible rate in the flux trap; however, the forethought of the reactor designers to include horizontal beam tubes and other experiment facilities in the reflector has enabled the mission capabilities to evolve as the neutron science research landscape has expanded and advanced since HFIR went critical in 1965. The current primary mission of providing neutrons for condensed matter physics research will continue to grow with improvements to HFIR facilities and detection instruments. The ability to damage materials with neutrons grows ever more important as the United States forges ahead with next-generation power reactor designs. The original isotope production mission will also continue to grow due to HFIR's efficient ability to produce high specific activities of desirable medical, industrial, and research isotopes.

Introduction

Neutrons have long been recognized as very valuable tools in probing the structure and dynamics of materials. Their unique properties of selectivity, magnetism, and neutrality make them useful in many diverse fields of science.

The need for a neutron source at the U.S. National Bureau of Standards was recognized and the initial planning for a reactor-based neutron science facility began in March 1958 with a construction permit being issued by the U.S. Atomic Energy Commission in 1963. This permit was converted to Operating License TR-5. The reactor achieved initial criticality on December 7, 1967 and began full-power operation at 10 MW on February 9, 1969. At the time, the US was building a new generation of high-performance research and test reactors: HFIR, HFBR, and ATR which all began operations at about the same time.

The NBSR received a 20-year extension of the existing operating license along with a power increase from 10 to 20 MW on May 16, 1984, and achieving 20 MW for the first time on April 3, 1985. In 1988, the National Bureau of Standards became the National Institute of Standards and Technology (NIST). Because of licensing concerns, it was decided at that time to retain the title of the reactor as the NBSR. There have been some suggestions that the acronym now stands for the 'Neutron Beam Split-core Reactor,' but the official title remains the 'National Bureau of Standards Reactor.' Another license renewal for 20 years of operation was granted on July 2, 2009 (NIST, 2004; Rush and Cappelletti, 2011).

Neutron research has always been the focus of the NIST Center for Neutron Research (NCNR). There have also been efforts in neutron activation analysis, development of standard reference materials, and some isotope production, but the main focus has been on neutron scattering. The NBSR thermal neutron scattering research was very successful and had a number of collaborative efforts in materials research.

The reactor was built with a large thimble for a cold neutron source adjacent to the reactor (shown in Fig. 1), but it was not until 1987 that a D₂O ice cold neutron source was installed, allowing new capabilities for research using longer wavelength neutrons. A guide hall with seven cold neutron guide tubes was completed in 1989, with first neutrons being received in 1990. In 1995, the cold source was upgraded, with the D₂O ice source being replaced by a liquid hydrogen source. This was again upgraded to an advanced liquid hydrogen source in 2002, and, in 2012, the guide hall was enlarged, and a second liquid hydrogen cold source was installed in a separate beam tube. Today, the NCNR has 24 cold neutron instruments, 6 thermal neutron instruments and hosts over 2500 research participants with over 300 research publications annually in the fields of biology, chemistry, condensed matter, engineering physics, measurements, soft matter, neutron physics and geology (NIST Center for Neutron Research, 2018).

Nuclear reactor design

Fuel element

The 1.75 m long NBSR fuel element, shown in Fig. 2, consists of 19 curved plates, of which the inner 17 contain U₃O₈ fuel plus aluminum dispersant with aluminum cladding. In these 17 plates, there are upper and lower fueled regions 33 cm length by 7 cm width with a 17.8 cm gap between upper and lower fuel regions, which allows for highly thermalized flux in the center of the core. Thus, there are a total of 34 individual fuel plates in each element. Each plate contains about 13 g of U₃O₈ and 19 g of Al in the 8.9 cm³ volume available for the fuel meat. Adding curvature to the plate minimizes the effects of heating on the

Fig. 1 Interior view of NBSR beam tubes, including the 55 cm cryogenic thimble, used for cold sources. Courtesy of NIST Center for Neutron Research.

Fig. 2 View of NBSR fuel element, with 17.8 cm central gap. NIST Center for Neutron Research (2004) *Safety Analysis Report for License Renewal for the National Institute of Standards and Technology Reactor (NBSR 14)*. Gaithersburg, MD: U.S. Department of Commerce.

mechanical joints that hold the fuel plates in place in the fuel element assembly. No burnable poisons or neutron moderators are added to the fuel elements. The fuel is enriched to approximately 93% and each element contains about 350 g of ^{235}U (NIST, 2004).

Coolant enters the internal passage of the lower adapter, flows up through the internal conical transition section, through the 18 channels defined by the curved fuel plates and unfueled curved plates of the lower fuel section, into and through the gap, through the 18 channels of the upper fuel section, and then out the upper adapter. The bottom adapters also act as check valves, allowing a small amount of upward coolant flow via hydraulic force against a spring when there is flow, but preventing the draining of the outlet side of the fuel elements if there is no flow.

Nuclear physics parameters

With the reactor operating at 20 MW, the peak thermal flux in the unfueled region at the core midplane is about $3.5 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$, with the thermal neutron flux being over four times the fast neutron flux. Nuclear physics parameters are listed in [Table 1](#) ([NIST, 2004](#)). These provide sufficient available reactivity that allows operation for a 38.5-day fuel cycle, while assuring a robust ability to shut down the reactor under all circumstances.

LEU conversion

Studies have shown that it will be feasible to use monolithic U-10Mo fuel with an enrichment of 19.75% in the same configuration as the existing HEU fuel, with slightly thinner fuel meat thickness. This 20 MW LEU core will have the same fuel cycle length and have almost identical shutdown margins as the HEU core. A Preliminary Safety Analysis Report for the use of this fuel was submitted to the U.S. Nuclear Regulatory Commission (NRC) in 2014 ([Brookhaven National Laboratory, 2014](#)). Conversion of the NBSR awaits qualification of this fuel and approval by the NRC. Thermal flux losses to the beam tubes of about 10% are expected with this conversion. This will be mitigated by the installation of a liquid deuterium cold source, detailed below.

Core configuration

The NBSR core, shown in [Fig. 3](#), is moderated and cooled with D₂O and consists of 30 fuel elements in a 3 concentric ring hexagonal pattern with the inner 2 rings having 6 fuel elements each and the outer ring having the remaining 18 elements. In addition, there are seven experimental thimble positions in a circular pattern about the core center, not currently in use. The center axial fuel gap, mentioned above, allows the installation of large radial beam tubes that surround the reactor and extend right to the edge of the core without looking at significant fast flux.

Running at 20 MW 24/7, the NBSR fuel cycle lasts 38.5 days. At this point, the reactor is refueled by removing four spent fuel elements and adding four new elements. Each fuel element in the reactor is cycled into a new position with each refueling, transitioning closer to the core center with each cycle. After running for either seven or eight cycles, the fuel elements are discharged. As a result of this fuel management scheme, the average ²³⁵U burnup in a 7-cycle element is 65% and the burnup in the 8-cycle elements is 71%, with a typical fission density of $1.9 \times 10^{27} \text{ fissions m}^{-3}$.

Reactivity control and safety systems

The NBSR is controlled by four shim arms, containing 0.2 cm thick cadmium clad with aluminum on both sides. Each shim arm is 2.54 cm thick by 12.1 cm wide with a poison length of 132 cm. Because of the need to minimize shadowing of the beam ports in the core center, movement of the shim arms are in a semaphore-type (angular) direction with an operational travel of 41°. The full-in position is 41° below horizontal. A reactor scram is accomplished by disengaging an electromagnetic clutch which, when energized, holds the shim arm in position against a ball screw jack and compression spring. Release of the clutch will result in complete shim arm insertion in less than 1 s. Neutron absorption by the shim arms is sufficiently large so that the reactor could be shut down by any one of them. Lowering the level of the D₂O in the vessel is an additional mechanism for emergency shutdown and provides sufficient negative reactivity to make the core subcritical even with all four shim arms withdrawn ([NIST, 2009](#)).

In addition to the shim arms, there is a fine-tuning regulating rod in the core, consisting of a solid aluminum cylinder 6.4 cm in diameter by 74 cm long. Displacement of the heavy water by aluminum and neutron absorption provides sufficient fine-tuning control.

Cooling systems

A simplified diagram of the D₂O primary system is shown in [Fig. 4](#). There is a total of four primary pumps (three normally in use) which drive a flow of about 560 l s⁻¹ into the main heat exchangers. Then the D₂O flows through a strainer to two inlet plena for the

Table 1 Summary of NBSR Nuclear Characteristics.

<i>Moderator and Coolant</i>	<i>D₂O</i>
Reactor power	20 MW

reactor vessel. The plena direct water up through the vessel into the core, with the flow being divided into an inner plenum of the inner six fuel elements (140 l s^{-1}), and the outer plenum of the remaining 24 elements (420 l s^{-1}). The coolant exits the fuel elements via the open top of the elements, then flowing to the bottom of the vessel where it exits through two outlet pipes. These are joined to a single outlet header containing a venturi for outlet flow measurements. The outlet header joins the suction header of the main circulating pumps, completing the cooling cycle. A closed helium sweep system is used to prevent degradation of heavy water isotopic purity and to minimize diffusion of tritiated heavy water vapor to the confinement building atmosphere as well as removing gases formed by radiolysis of the primary coolant and recovering any heavy water lost due to evaporation.

The D_2O system also contains a purification loop, an experimental cooling loop for cooling the cold source cryostats, and also supplies reserve D_2O to external and internal emergency cooling tanks. The main heat exchangers are located in the process room in the basement; the entire D_2O system is within the confinement building.

A thermal shield is installed just outside the reactor vessel, consisting of a 5 cm thick lead shield, which absorbs gammas from the core, preventing thermal damage to the concrete biological shield. The thermal shield is cooled by a series of 188 water (H_2O) cooling lines imbedded in the lead. Heat is transferred to the secondary cooling system via a plate-and-frame heat exchanger.

The secondary system removes heat from the primary coolant systems as well as several ancillary systems. System flow is generated by three of four main secondary pumps, with a nominal flow of about 660 l s^{-1} . The heat load assumed by the secondary coolant is transferred to the atmosphere via two cooling towers, a hybrid wet/dry tower with three cells and a smaller tower with two cells erected to provide additional cooling capacity. The secondary pumps and several additional auxiliary pumps are located in a separate building adjacent to the cooling towers.

Experiment systems

The layout of NCNR neutron instruments is shown in Fig. 5. There are five thermal neutron scattering instruments and one thermal radiography instrument (BT2), labeled BT1 through BT8, whose beams are aligned with the D_2O (non-fueled) gap between the upper and lower fuel sections of the core. In addition, there is a single instrument which uses cold neutrons from a small liquid hydrogen cold source in BT9. The remaining 23 neutron scattering instruments, listed in Table 2, all use cold neutrons emanating from a liquid hydrogen cold source, which can be seen in Fig. 3.

The liquid hydrogen cold source consists of a cryostat with a 3 cm annulus of liquid hydrogen. This is connected to a helium-cooled condenser mounted on the face of the reactor above the cryostat. Liquid hydrogen flows from the condenser to the cryostat via a natural convection thermosiphon loop wherein hydrogen vapor produced in the cryostat moves up to the condenser, completing the cycle.

Replacement of the cold source with a liquid deuterium cold source is planned for 2023. This will result in a gain of up to a factor of 2 for long wavelength/low energy neutrons ($> 5 \text{ \AA}$ or $< 4 \text{ meV}$) and is intended to mitigate the effects of the thermal neutron flux loss upon conversion of the core to LEU fuel. The proposed liquid deuterium cold source will contain a volume of about 35 l of liquid deuterium, compared with about 5 l in the current liquid hydrogen cold source. This is shown in Fig. 6. This will result

Fig. 6 NBSR core, showing large proposed liquid deuterium cold source (left) and small liquid hydrogen cold source (right). Courtesy of NIST Center for Neutron Research.

in the cold source heat load increasing from about 3 kW to about 6 kW. A new 7 kW helium refrigeration system was installed in 2018 in preparation for the upcoming deuterium cold source installation and eventual conversion to LEU.

Most of the beam time on NCNR instruments is made available through a peer-review proposal process. The NCNR issues calls for proposals approximately twice a year and proposals are reviewed at several different levels by both outside reviewers, NCNR staff, and a Beam Time Allocation Committee.

There are several sponsors of neutron instruments at NCNR, including the Center for High Resolution Neutron Scattering (CHRNS), which is jointly funded by the U.S. National Science Foundation. CHRNS supports a portfolio of neutron instruments at NCNR and provides capabilities for a very diverse scientific program in material science, chemistry, biology, geosciences and condensed matter physics. CHRNS also supports a variety of educational programs and activities, including a summer school on “Methods and Applications of Neutron Spectroscopy” for graduate and post-doctoral students ([NIST Center for Neutron Research, 2018](#)).

Glossary

Reactivity A measure of the deviation of the reactor core from a critical state in which the rate of neutron generation equals the rate of neutron loss; that is, the fission rate is constant and the so-called effective multiplication factor, k_{eff} , is 1.0. Reactivity is sometimes measured in units of $\$$'s, where a $\$1$ increase in reactivity implies that the chain reaction can be sustained by only the prompt neutrons; that is $k_{\text{eff}} = 1 + \beta$ where β is the fraction of the delayed neutrons (emitted from certain fission products). For ^{235}U $\beta = 0.0064$.

Introduction

The Annular Core Research Reactor (ACRR) is a unique, one-of-a-kind nuclear reactor facility operated by Sandia National Laboratories (SNL) for the National Nuclear Security Administration that is considered by many to be a national treasure. There is no other research reactor in the world that has the attributes and capabilities comparable to that of the ACRR. The ACRR was specifically designed to meet the irradiation testing needs of the U.S. nuclear defense program. The ACRR has four major attributes that make it unique: (1) a large (9", 22.86 cm) dry central cavity; (2) an epithermal neutron flux; (3) a large pulsing capability; and (4) a fueled-ring external cavity with a larger (20", 50.8 cm) dry cavity.

The ACRR is typically used to perform irradiation testing when a high neutron fluence is required over a short period of time. Historically, the ACRR has been used for a wide variety of experiment campaigns in addition to supporting its main mission—irradiation services of components for the nuclear defense program. Some of these campaigns have included radiation damage in materials testing, nuclear pumped laser testing, nuclear fuels testing, space nuclear thermal propulsion testing, and medical isotopes production.

The ACRR is located in Technical Area V (TA-V) at Sandia National Laboratories in Albuquerque, New Mexico. The ACRR is currently fully operational. The reactor, in its current fueled configuration, was assembled in 1978 to accommodate large experiments at the center of its core and have large pulsing capabilities. The fuel elements for the ACRR are similar in size and shape to TRIGA fuel (Reese, 2021). However, the fuel is unique in that the form of the fuel is uranium dioxide/beryllium oxide (UO₂-BeO) that was specially designed to have a large heat capacity in order to allow for larger pulsing capabilities as compared to other TRIGA-like pulsed reactors. This type of fuel, containing beryllium oxide, is no longer capable of being produced anywhere in the world.

ACRR description

The ACRR can operate in a pulse or steady-state mode. Most customers desire the pulsing capabilities of the reactor. This has allowed the ACRR to have no significant fuel burnup over its 40 years of use. Under the same operating conditions, the reactor fuel is expected to last at least another 40 years. Fig. 1 shows the ACRR looking into the pool during a 2 MW steady-state power operation. The ACRR core is shown on the left in the figure. The 9-in. (22.86 cm) diameter dry cavity extends from above the pool through the center of the core. The reactor facility also accommodates the fueled ring external cavity-II (FREC-II), shown on the right in the figure, which maintains a larger 20-in. (50.8 cm) diameter dry cavity and uses uranium/zirconium-hydride (UZrH) TRIGA fuel as a subcritical multiplier. As currently configured, the FREC-II is not capable of achieving nuclear criticality. FREC-II provides experimenters with a larger test volume, and the fuel arrangement limits the neutron fluence gradient across the test volume. The TRIGA fuel used in FREC-II was originally used in ACRR's predecessor core, the Annular Core Pulse Reactor.

The dry central cavity extends from above the pool and goes directly through and below the core region. Another view of the ACRR and FREC-II is shown in Fig. 2, with the reactor shut down, FREC-II (on the left) tilted back in its "decoupled" configuration, and the radiography tube on the right.

The ACRR core is located in an open pool 10 ft (3.0 m) in diameter and 28 ft (8.5 m) deep. The pool is filled with 64,000 L of deionized water. The core is cooled by natural convection of the pool water. The pool water is cooled by a heat exchanger and cooling tower. For steady-state mode operations, the ACRR operates continuously up to 4 MW. The pool heat rejection system is rated to support steady-state operations up to 5 MW.

The ACRR is fueled by a 236-element array of UO₂-BeO fuel elements. The fuel is uranium enriched to 35 wt% U-235, with 21.5 wt% UO₂ and 78.5 wt% BeO. The ACRR fuel elements are stainless steel clad, 1.5 in. (3.8 cm) in diameter and 21 in. (53.34 cm) in fuel length. Within the elements are niobium cups that hold the UO₂-BeO fuel pieces. The ACRR is controlled by two fuel-followed safety rods, three poison (void-followed) transient rods, and six fuel-followed control rods. The control rods (safety and control) make up part of the 236 elements for the normal core configuration.

- 236 UO_2 -BeO fueled elements
1.5 in (3.8 cm) dia. x 20.5 in (52 cm)
100 g U-235 per element – 35% enriched
- Operating Power level
2-4 MW_{th} Steady-State Mode
300 MJ Pulse Mode (6 ms FWHM)
300 MJ Transient Mode (Programmable)
- Dry cavity 9 in (23 cm) diameter
Extends full length of pool through core
Neutron Flux $4\text{E}13 \text{ n/cm}^2\text{-s}$ at 2 MW
Neutron Fluence $6\text{E}15 \text{ n/cm}^2$ at 300 MW
90% > 1 eV, 58% > 10 keV, 46% > 100 keV
- Epithermal/Fast Spectrum
Flux in cavity can be tailored for desired energy spectrum (Poly, B4C)
- Open-pool type reactor
Core cooled by natural convection
Pool cooled by HX and cooling tower
- FREC-II uses previous ACPR fuel
TRIGA type (UZrH)
Dry cavity 20 in (51 cm) diameter
- Fuel burnup is minimal
- Reactor used for short duration power runs, pulses, and transients

Fig. 1 The ACRR and FREC-II operating at 2-MW steady-state power.

Fig. 2 ACRR with FREC-II decoupled.

The ACRR central cavity and FREC-II cavity allow for a high degree of experiment flexibility, along with in situ and real-time experiment instrumentation and diagnostics. The large volume of the cavities allows for the possibility of acceleration/deceleration (High-G) apparatus, flow loops and other complex experimental hardware to be fielded within the high-fluence region of the core. Because the ACRR is under-moderated, the neutron spectrum has a large epithermal component within the central cavity. This epithermal spectrum can be modified using thermal absorbers to harden the spectrum or by the use of moderator materials to give a softer spectrum. The ACRR can operate in a steady-state, transient, or pulse mode. In the steady-state mode, the operating power level is limited to $\sim 4 \text{ MW}$. In the pulse mode, a maximum pulse yield of $\sim 300 \text{ MJ}$ (resulting from reactivity insertion of $\$3.50$) with a full-width half-maximum (FWHM) of 6.8 ms can be attained. In the transient mode, the reactor power shape can be tailored to the desired requirements for a total reactor energy yield of $\sim 300 \text{ MJ}$. The transient mode can be used to increase the reactor power quickly, as in a linear ramp increase in power levels from low to high power level.

Cavity spectrum modification capability

The ACRR maintains an epithermal neutron fluence spectrum in the core and central cavity. This allows for the neutron fluence energy spectrum to be tailored to the desired specifications of an experiment. Moderators can be used within the cavity to thermalize the neutron spectrum. These spectrum modifiers are referred to as “buckets.” Polyethylene or water can be added to a bucket environment in an annulus geometry to increase the thermal neutron population. Boron and lead can be used to increase the fast neutron fluence ratio and decrease the gamma-ray fluence, respectively. Boron can be added to a bucket environment in an annulus geometry to remove the thermal neutron population. Gamma rays can be attenuated or increased by adding lead or cadmium, respectively, in an annulus geometry. These perturbations allow for the neutron to gamma ray ratio to be modified in the cavities, adding to the versatility and flexibility of the ACRR to meet the customer’s radiation testing requirements.

In addition to the free-field irradiation condition (no bucket environment) of the ACRR and FREC-II cavities, several buckets exist and are available for use by the experimenter to allow for neutron and gamma-ray spectrum modification. New buckets can also be built and tested as future needs are required by the experimenters. The irradiation space within each bucket is thoroughly characterized prior to use in order for the experimenter to have the utmost confidence in the neutron and gamma ray irradiation conditions. Characterization involves both MCNP modeling and experimental testing (Parma et al., 2013, 2015a,b, 2016a,b, 2017). ACRR test measurements in the irradiation volume includes using neutron activation analysis of foils and pellets, irradiation of thermoluminescent dosimeters (TLDs), and active measurements using calorimeters, photo-conducting diodes (PCDs), self-powered neutron detectors (SPNDs), and fission chambers. The neutron energy spectrum is adjusted using least-squares fitting techniques with activation foil measurements to produce the characterized neutron spectrum at the irradiation location within a bucket.

Figs. 3–7 show the neutron energy spectrum and the prompt gamma energy spectrum for the ACRR cavity free field, PLG bucket, LB44 bucket, Cd-Poly bucket, and the FREC-II cavity free field axial centerline positions. Fig. 8 shows simplified drawings of some spectrum modifiers. As previously discussed, the use of polyethylene, boron, cadmium, and lead can significantly alter both the neutron spectrum and the gamma-ray spectrum and magnitude. The PLG bucket enhances the thermal neutrons and reduces the gamma-ray intensity as compared to the free field case. LB44 removes the thermal and some of the epithermal neutrons and reduces the gamma-ray intensity as compared to the free field case. Cd-Poly removes the thermal neutrons and enhances the gamma-ray intensity. The FREC-II cavity has a greater thermal neutron component as compared to the ACRR cavity.

Fig. 3 Neutron and prompt gamma-ray energy spectra for the central cavity free-field environment.

Fig. 4 Neutron and prompt gamma-ray energy spectra for the polyethylene-lead-graphite (PLG) bucket environment.

Fig. 5 Neutron and prompt gamma-ray energy spectra for the Lead-Boron (LB44) bucket environment.

Fig. 6 Neutron and prompt gamma-ray energy spectra for the Cadmium-Polyethylene (Cd-Poly) bucket environment.

Fig. 7 Neutron and prompt gamma-ray energy spectra for the FREC-II cavity free-field environment.

Table 1 shows some of the important metrics associated with the bucket environments that are of interest to experimenters. These metrics include the total neutron fluence, the 1-MeV damage equivalent in silicon (DES) neutron fluence, the prompt gamma-ray absorbed dose in silicon (Si), and the ratio of the 1-MeV DES neutron fluence to the prompt gamma-ray dose. From this table the largest 1-MeV DES neutron fluence attainable is $\sim 8.2\text{E}12 \text{ n/cm}^2$ per MJ. The largest prompt gamma-ray dose is $\sim 11 \text{ k}_{\text{rads}}$ (Si) per MJ. The 1-MeV DES fluence to gamma-ray dose can be varied by about a factor of 13, with the Cd-Poly bucket having the smallest ratio and the LB44 bucket having the largest ratio.

Fig. 8 ACRR spectrum modifiers.

Table 1 Neutron fluence and prompt gamma-ray dose for the characterized environments.

Bucket Environment	Neutron Fluence Total (n/cm^2 -MJ)	Neutron Fluence 1-MeV DES (n/cm^2 -MJ)	Prompt Gamma-Ray Dose in Si (k_{rad}/MJ)	Ratio of 1 MeV DES Fluence to Gamma-Ray Dose (Si) $\times 1E+12$
Central Cavity Free Field	$2.05E+13$	$8.19E+12$	7.94	1.03
PLG	$2.12E+13$	$6.90E+12$	6.10	1.13
LB44	$1.15E+13$	$6.47E+12$	0.98	6.60
Cd-Poly	$1.26E+13$	$5.24E+12$	11.05	0.47
FREC-II Free Field— FREC Rods Up	$3.98E+12$	$1.34E+12$	1.71	0.78

Table 2 Neutron Fluence and Prompt Gamma-Ray Dose for Free Field ACRR and FREC-II Cavities for a 300 MJ Maximum Pulse.

Environment	Neutron Fluence Total (n/cm^2)	Neutron Fluence 1-MeV DES (n/cm^2)	Prompt Gamma-Ray Dose in Si (k_{rad})
Central Cavity Free Field	$6.15E+15$	$2.46E+15$	$2.38E+03$
FREC-II Free Field - FREC Rods Up	$1.19E+15$	$4.02E+14$	$5.13E+02$

Table 2 shows the neutron fluence and gamma-ray dose for a 300 MJ pulse for the ACRR and FREC-II free-field environments. For a maximum pulse, the total neutron fluence in the ACRR central cavity is $6.15E15$ n/cm^2 , the 1-MeV DES neutron fluence is $2.46E15$ n/cm^2 , and the prompt gamma-ray dose in Si is $2.38E3$ k_{rad} s. For a 300 MJ pulse, the peak power level attainable is $\sim 50,000$ MW, corresponding to a neutron flux of $1.0E18$ n/cm^2 -s.

Pulsing capabilities

Pulse mode capability

The ACRR has unique pulse mode capabilities, significantly greater than other pool-type pulse reactors. The three pulse rods can be simultaneously or sequentially ejected from the core region using a pneumatic ejection system, within ~ 80 ms. A maximum pulse at the ACRR is a reactivity addition of $\$3.50$, producing a pulse width of 6.8 ms, a peak power of $\sim 50,000$ MW, and a total reactor

energy deposition of 300 MJ. This is at least three times larger than what TRIGA-type reactors can attain. Smaller pulses, as low as 10 MJ, can also be attained with the ACRR. Fig. 9 shows the experimental results for several different size pulses for the ACRR. The full-width half-maximum (FWHM) for a pulse is directly proportional to the neutron generation time for the reactor, and inversely proportional to the reactivity added. For reference, a 300 MJ pulse yield from a reactivity insertion of \$3.50 would produce a FWHM pulse width of ~ 7 ms; a 100 MJ pulse (\$2.05) would have a pulse width of ~ 14 ms; and a 50 MJ pulse (\$1.40) would have a pulse width of ~ 32 ms. With spectrum modifying buckets inserted in the central cavity, the pulse characteristics do not change significantly because the neutron generation time does not change appreciably. With FREC-II coupled to the ACRR and the FREC rods in the “down” position, the pulse characteristics are also similar. With the FREC-II coupled to the ACRR and the FREC rods in the “up” position, the neutron generation time increases to ~ 32 μ s, from ~ 24 μ s for the ACRR with FREC-II decoupled, and the pulse width increases proportionately.

Transient mode capability

The ACRR also has unique transient mode capabilities. The three pulse rods can be driven out of the core using stepper motors as opposed to pneumatically ejected. Under these conditions, up to \$4.25 of reactivity can be inserted incrementally over time. Power ramps and steady-state transients can be generated for up to 300 MJ of reactor energy. An example is an instantaneous step power of 50 MW that can be held constant for 6 s, or 100 MW for 3 s in order to achieve the 300 MJ of energy. These types of conditions are typically desirable for advanced fuels testing experiments where the cladding or fuel material integrity of the test specimen is desired to be challenged.

Double pulse mode capability

The ACRR also has unique double-pulse mode capabilities. Using the pneumatic ejection system, the three pulse rods can be simultaneously ejected from the core for a single pulse or timed for a unique double pulse. Each of the pulse rods is worth greater than

Fig. 9 ACRR pulsing characteristics.

\$1.00 of reactivity allowing for one rod to be ejected, followed by the other two. This capability is desirable for experiments where rapid heating is desired in an experiment, followed by an additional pulse.

Conclusion

The ACRR with its FREC-II subcritical multiplier is a unique research reactor facility unlike any other in the U.S. Its large pulsing capabilities and dry irradiation cavities allow for both passive and active experiments to be fielded at the peak neutron and gamma-ray flux in the core. Its epithermal/fast neutron spectrum in the central cavity allows for neutron spectrum modification and gives experimenters the ability to attain their unique irradiation requirements. The ACRR will continue to provide invaluable pulse and steady-state irradiations services to the U.S. defense program for at least another 40 years.

History

The first Russian research reactor, F-1, was commissioned in 1946. It was used only for the demonstration of sustainable nuclear fission chain reaction. Later in the 1950s and 1960s, Russian designers developed many diverse research reactors projects which demonstrated the vast creative potential of the national school of nuclear engineering. In the early 1950s the development of nuclear power program began in USSR. It became absolutely necessary to create powerful material testing reactors for the study of structural and fuel materials intended for the use in nuclear power reactors, propulsion facilities and other installations. The study of such materials for reactors with different types of coolant (water, liquid metal, gas) required the creation of channels equipped with autonomous circulation circuits called “loops.” In 1952, the Laboratory $\mathcal{N}^{\circ} 2$ (now the National Research Centre “Kurchatov Institute”) brought into the action the RFT—a material testing loop-type reactor which gave rise to extensive studies on the behavior of reactor materials and provided essential data for the design of different nuclear reactors. But experimental capabilities of this reactor were insufficient keeping in mind the proposed intensive development of fuel and structural materials for nuclear power facilities. By this reason it was necessary to replace a reactor RFT for a new more powerful loop-type reactor.

The idea of designing a new reactor for to carry out experimental activities in the field of atomic energy belongs to academician I.V. Kurchatov, scientific leader of Russian nuclear program. In 1956, at his suggestion, the Institute of Atomic Energy (IAE, former Laboratory $\mathcal{N}^{\circ} 2$) began a reactor feasibility study called MIR. Then in 1958, NIKIET, the leading Russian nuclear designer organization started designing the reactor MIR under the scientific supervision of IAE.

However, in 1960 IAE also began the development of a loop-type material testing reactor MR to replace the reactor RFT that was finally shutdown in 1962. The development of MIR and MR reactors occurred in parallel. It was a very productive competition between the two projects. The physical startup of the MR reactor in IAE was held in December 1963, and full power achieved in July 1964. The physical startup of the MIR reactor took place on December 24, 1966; the reactor was brought to full power on August 11, 1967.

After commissioning of these reactors, they provided almost all the reactor material testing research in the USSR for nuclear power and other tasks until the early 1990s when MR reactor was permanently shut down and the MIR reactor became the main Russian material testing reactor. At this time, the power level of MIR was raised to 100 MW.

The MIR (later renamed to MIR.M1) research reactor is a heterogeneous, loop, channel, thermal neutrons reactor installed in a water pool (Arkhangelsky et al., 2012; Fedulin and Vinogradov, 2016). It is designed for:

- loop tests of fuel elements and fuel assembly mock-ups of different nuclear reactor types;
- tests of structural and absorbing materials and products of different nuclear reactor types and purpose;
- production of radionuclides.

At first, the reactor had four core loop channels connected in pairs to two loops installed by that time: water loop PV-1 and steam-water loop PVK-1 of 2 MW capacity each. Later two 500 kW loops with a lead-bismuth coolant, each having one experimental channel, were put into operation as well as a 2 MW sodium-cooled loop with two loop channels. Once one more channel was connected to the water and steam-water facilities, the total number of loop channels in the core achieved 10.

In 1975, the reactor was refurbished and changed the name to MIR.M1. As a result, each loop channel was surrounded with six fuel assemblies and four or five control rods. It made it possible to make all the core loop cells practically equivalent and to improve the regulation of the test modes in each of the channels. After the refurbishment, the reactor was equipped with water loops PV-2 and PVK-2. After the start of the fast reactor BOR-60, also in RIAR, the sodium-cooled loop was converted into a loop with a high-temperature organic coolant.

In 1983, a loop with a steam-water coolant PVP-1 was commissioned with parameters close to those of the RBMK reactor coolant. In 1989–1990, the following loop facilities were commissioned: gas-cooled loop PG-1 and steam-water-cooled loop

PVP-2. Their sealed containments serve as additional safety barriers. It allows conducting specific experiments to simulate and study accidents of fuel elements in the loop channel.

Future prospects

Constantly conducted systematic and purposeful work on the improvement and extension of the reactor lifetime will allow operating the MIR.M1 reactor for research purposes up to 2027.

In 2016 RIAR received designations as IAEA International Centre based on Research Reactor (ICERR). Designation of RIAR as the IAEA ICERR confirmed its worldwide recognition as a reputable research organization. Reactor MIR.M1 includes in the perimeter of ICERR.

Future perspectives of the utilization of MIR.M1 reactor deal with the irradiation tests of materials for innovative water-water reactors such as VVER-C, VVER-SCWR in particularly:

- in-pile testing and research in developing the promising structural materials for Gen IV reactors;
- lifetime extension for the existing water-cooled power reactors;
- development and pilot demonstration of innovative nuclear technologies.

The MIR.M1 reactor used in the research with IAEA, China, Republic of Korea and other countries. The international cooperation activity includes bilateral commercial contracts for in-pile experiments and post irradiation experiments of structural, fuel and absorbing materials in support of innovative fission reactor technologies; long-term research programs for innovative light water reactor materials under way based on national programs and bilateral commercial contracts (Accident Tolerant Fuel Concepts, radiation resistant steels for light water reactor vessel and in-vessel devices, etc.); irradiation research and post irradiation experiments of materials and elements of equipment to be used in prospective fusion projects; long-term national research programs on radioactive wastes, spent fuels and minor actinides management technologies and bilateral commercial contracts.

Reactor fuel

The fuel for Russian reactors and MIR.m1 is fabricated according to original Russian extrusion technology (Alexandrov et al., 1996). This technology was successfully developed in Russia from beginning of 1950s and has made significant progress. This technology allows producing tubular fuel elements of various shapes adapted to different reactors and experimental devices. A MIR.M1 assembly is shown in Fig. 1. (See Table 1.)

A MIR.M1 element is structurally made from 4 coaxially located annular fuel elements fastened in the upper and lower grids. Each fuel element is a three-layer tube, in which the fuel layer from both sides is enclosed into the aluminum alloy cladding. In the cavity of the inner fuel element there is an annular aluminum displacer $\varnothing 34 \times 2$ mm. The fuel elements are 2 mm thick and on the outer surface along the whole length there are three azimuthally oriented ribs. The outer fuel element is 70 mm in diameter. Height of the fuel is 1000 mm. The fuel material is UO_2 of 90% ^{235}U enrichment in aluminum matrix. The fuel layer is 0.56 mm thick, the claddings are 0.72 mm thick and made of aluminum alloy. Inter fuel element gap is 2.5 mm. In total one fuel assembly contains 345–350 g of ^{235}U .

The MIR.M1 reactor uses highly enriched uranium (HEU) and Russian researchers participate in the uranium enrichment reduction program for research reactors (Podvig, 2017). From 2010 they have investigated consequences of the reactor conversion from HEU to low enriched uranium (LEU). To compensate for additional neutron absorption in ^{238}U after the conversion, it will be necessary to increase the density of ^{235}U from 0.9 to 1.0 g cm $^{-3}$ and total uranium density from 1.0 to 5.2 g cm $^{-3}$, respectively. For this purpose the material of the meat will change from UO_2 to U-Mo both in aluminum matrix.

Core configuration

By physical features, the MIR.M1 reactor is a thermal heterogeneous reactor with a moderator and a reflector made of metallic beryllium and water coolant. According to its design features it is a channel-type reactor located in a pool with water. Such design allowed for a combination of the main advantages of pool-type and channel-type reactors. A fundamentally new designer solution of the reactor MIR.M1 is the withdrawal of loop channels pipelines from the reactor into dry chambers under the pool water layer. It reduced the overall dimensions of the loop channels, simplified the reloading operations and improved operation and maintenance safety (Fig. 2).

The MIR.M1 core is arranged of hexagonal blocks of beryllium stacked along the axis of which straight-through zirconium alloy channels are installed to accommodate working and experimental fuel assemblies. The core design is chosen based on the condition of minimal mutual influence of neighboring test rigs since their operation modes can differ greatly. Over time, the beryllium has a negative effect on the operation of the reactor due to the accumulation of byproduct nuclides such as ^8Li and ^3He which are strong neutron absorbers. This effect reduces the reactivity margin and increases the power perturbation across the core.

Table 1 MIR.M1 reactor parameters.

Name	Units	Value
Thermal power, max.	MW	up to 100
Maximum power of working channel	MW	3.2
Loop channel diameter, max.	mm	120
Core height	mm	1000
Number of loop channels, max.		11
Thermal neutron flux density, max.	$\text{cm}^{-2} \text{s}^{-1}$	5×10^{14}
Fast neutron flux density, max.	$\text{cm}^{-2} \text{s}^{-1}$	1×10^{14}
Average volumetric power	MW l^{-1}	0.85
Coolant:		water
pressure at the reactor inlet	M Pa	1.25
temperature at the reactor inlet	K	303–343
temperature at the reactor outlet	K	up to 371
Operation cycle duration	days	up to 40

Fig. 2 MIR.M1 reactor cross-cut. (1) control rods drives; (2) divided inlet manifolds; (3) core; (4) outlet pipelines; (5) ionizing chamber.

Simultaneously in the reactor there can be performed tests of several trial fuel assemblies and experimental devices differing by the design, material composition, content of fissionable materials in fuel elements, power, type and parameters of the coolant. The main requirement set to the reactor is the possibility of provision, maintenance and control of the specified irradiation conditions simultaneously for all the investigated fuel assemblies. According to the reactor purpose the core structure is chosen from the condition of minimum mutual effect of the adjacent loop devices, since their operation modes can significantly differ. The cartogram of the MIR reactor core is presented in Fig. 3.

Control and safety rods

The distinctive peculiarity of the MIR reactor is the use of a great number of control rods. It is related to the necessity of creation of the energy release profile providing and maintaining the experimental work. These control rods are located in zirconium channels at the edges of the adjacent beryllium blocks. They are distributed by the performed functions as follows:

- 2 automatic control rods (AC);
- 27 safety rods and shim rods (SR-ShR).

The control scheme provides the possibility of selection of any 6 rods from 27 as safety rods (SR).

Fig. 3 Reactor core cartogram. (1) Core Be-block; (2) reflector Be-block; (3) loop channel Be-block; (4) emergency control rod; (5) operating channel; (6) channel for additional loading; (7) ionizing chamber; (8) loop channel; (9) scram rod; (10) core Be-plug; (11) reflector Be-plug; (12) control rod tube; (13) control rod with a plug; (14) Al-plug.

Reactivity compensation is also made by compensators that are located in the central channels of beryllium blocks of the core stacking peripheral row.

The shim and safety rods present the design consisting of the jointly connected parts: double-element absorber and displacer. On the upper SR end there is an adapter, with the help of which it is weighed to the drive exhaust. All SR units are connected to each other by spherical joints.

The SR absorbing part consists of two jointly connected cylindrical absorbing elements with nominal length of the absorber - 512 mm each. The absorbing element consists of the cladding having the outer diameter of 24 mm and wall thickness of 0.5 mm made from stainless steel. In the inner cladding cavity there is a fuel column from inserts of dysprosium titanate ($\text{Dy}_2\text{O}_3 \times \text{TiO}_2$) with diameter of ~ 22.8 mm, density of $6.0\text{--}6.3 \text{ g cm}^{-3}$. On top above the absorber column there is a gap for compensation of thermal lengthening and swelling of the absorber.

The absorber unit consists of a rod with diameter of 9 mm made from the zirconium alloy, on which bushes are threaded that supported by the lower plug. The bushes have the outer diameter of 24 mm and are made from CAB1 aluminum alloy. The displacer is 1100 mm long.

MIR.M1 experimental capabilities

The MIR.M1 reactor was designed to test experimental fuel, fuel assemblies and structural materials of various nuclear installations (power, propulsion) operated under different loads in different coolants (water, liquid metals, gas, organic compounds). The main feature of the reactor is 11 experimental loop channels in the core connected to autonomous loop facilities with different types and parameters of coolants to perform testing under various thermal and hydraulic modes.

Key areas of research at the reactor:

- tests of fuel elements and fuel assemblies under designed conditions for the cores of advanced reactors of increased safety;
- tests of irradiated and unirradiated fuel elements under accident-simulating conditions;
- study of behavior of leaky fuel elements under stationary and transient conditions.

Irradiation of promising fuel elements with claddings from improved alloys and fuel compositions based on intermetallics and cermets.

Irradiation and post-irradiation examinations of loop fuel assemblies of various types that were used in experiments with power ramps, loss of cooling and simulated leakage of fuel rod claddings.

At present, seven loop facilities are under operation at the MIR.M1 reactor, each connected to one or two loop channels.

Introduction

History of nuclear research and development in Belgium

The history of nuclear R&D is mostly the history of the Belgian Nuclear Research Centre, today known as SCK•CEN (Verwimp and Verledens, 2002). Today as in the past SCK•CEN plays a central role in research and development on the applications of nuclear technology and the effects of radiation, reaching out to academics, industry and research institutes in Belgium and abroad.

In September 1951, Pierre Ryckmans commissioned a group of scientists to set up a new organization to study the applications of nuclear energy. The founders came from various circles of the scientific world, universities, government and industry. After consultations they decided to set up a non-profit association that would be called “Studiecentrum voor de Toepassingen van de Kernenergie” (Research Centre for the Applications of Nuclear Energy) or abbreviated to STK. The choice of this form of company shows that they wanted to stimulate the peaceful development of nuclear energy in the public interest. The statutes were published in the Staatsblad (State Gazette) of April 19, 1952.

In 1954, construction at the site of Mol started. On Friday May 11, 1956, the BR1, Belgian Reactor 1, produced its first chain reaction. The reactor used graphite as a moderator, natural uranium as nuclear fuel and air as the coolant, with a power of 4 MW. The first design of the reactor was installed in Rhode-Saint-Genèse and was built in the premises of the “Administratie voor Luchtvaartkunde” (Department of Aeronautics). The employees of the Centre carried out the final design in close co-operation with specialists from Harwell (United Kingdom) and Belgian engineering consultancies. The BR1 reactor is still operational today.

After the successful start-up of the first nuclear reactor in Belgium, the research center decided to construct a high flux test facility, the BR2 (Fig. 1) and a nuclear power reactor, the BR3. The former would be a complement to the BR1 low flux reactor in order to support the development of nuclear energy applications in Belgium. The latter was initially planned to supply energy to the 1958 world exhibition in Brussels, but this plan was cancelled and the plant, the first pressurized water reactor on the European continent, was constructed in Mol as the BR3 reactor.

On July 23, 1957 the Royal Decree that set up the Belgian Nuclear Research Centre as an organization of public benefit with a legal personality appeared in the Belgisch Staatsblad (Belgian State Gazette). The new statutes of the organization described the role of SCK•CEN as follows:

- The collecting and keeping of scientific and technical documentation relating to the application of nuclear energy;
- Undertaking research of a scientific and technological nature regarding applied nuclear energy;
- Stimulating the training of specialized personnel relating to the application of nuclear energy;
- Performing supervisory and monitoring operations of a technical nature.

In the second half of the 1960s, facilities for studying and demonstrating options for the nuclear fuel cycle were established, as well as laboratories to study the effect of irradiation on materials and on living organisms. A pilot fuel reprocessing plant and

Fig. 1 Schematic of the BR2 reactor, showing its particular geometric design with the central beryllium matrix, containing the 79 irradiation channels.

underground laboratory complemented this infrastructure in order to support studies on the closed fuel cycle for nuclear power. This effort was part of the European development of nuclear power generation, following different reactor technical paths, including light water reactor, gas cooled reactors and liquid metal cooled reactors.

Since the 1970s, Belgium installed nuclear power generation capacity to cover about 55% of the electricity needs. Belgium is also one of the world's leading suppliers of radio-isotopes for industrial and medical use. The institute for Radio Elements (IRE) was established for conditioning, distributing and commercializing radioisotopes, mainly for medical applications, and also for developing applications in other fields, for example for the biomedical and industrial sector. SCK•CEN was responsible for the production.

Operational history or milestones of significance

The first criticality of the BR2 reactor was reached on July 6, 1961. This event was preceded by a design and construction period, which started in 1956. The Belgian Nuclear Research Centre contracted Nuclear Development Corporation of America in White Plains (New York, USA) to design the BR2. Managers of the STK, engineers from industry, engineering consultants and electricity producers took part in the design. The unique design of the BR2 is shown in **Fig. 1**. The construction of the reactor began in September 1957. In support of the commissioning and later operation, a zero power assembly, the BR02, went into operation at the end of 1959.

Belgian industry was used as much as possible for the construction of the reactor. On July 6, 1961 BR2 produced its first chain reaction. The Prime Minister, the chairman of EURATOM, the American ambassador and a representative of the Ministry of Economic Affairs attended the event. The reactor was further tested and was declared fully operational in December 1962. Irradiation experiments began in January 1963 and have continued to today. In 1971, the cooling capacity of the primary and secondary circuits was increased to 125 MW. The beryllium matrix was replaced for the first time from 1979 to 1980.

Since 1986, the BR2 reactor has been subject to decennial safety reassessments required by the regulator. The initial design life of 25 years has been extended under the same regulations as for the nuclear power plants and all class 1 nuclear facilities in Belgium.

There is currently no end date for operation of the BR2 in the license. The periodic safety reassessments are imposed by Belgian regulation, implementing the European Council directive 2014/87/EURATOM. The content of the safety reassessment is defined following the IAEA guide SSG-25.

In 1995, the beryllium matrix was replaced for the second time. The matrix of the BR02 zero power mock-up was inserted into the reactor and the BR02 was dismantled. Physics testing to determine core characteristics are now measured utilizing the BR2 reactor at zero power. The reactor was restarted in 1997 after a successful refurbishment.

For the 2016 periodic safety reassessment, a formal ageing management program was established for the BR2 reactor. The outcome of this program resulted in a second refurbishment program with replacement and modernization of many components (Van Dyck, 2017). As a consequence of the European Stress Test that became required after the Fukushima Daichi accident in 2011, additional improvements were made. A new and upgraded emergency electricity feed network was installed in support of defense in depth criteria for the passive safety system of the BR2 reactor.

In 2016, the BR2 reactor restarted and was again the most powerful operating research reactor in Western Europe. The 2016 periodic safety reassessment covers the operational period up to 2026 and the strategy for operation until 2036 is currently under preparation.

How the facility mission or design has evolved over its lifetime

The initial mission of the design of the facility was expressed in the initial mission to the reactor designer, “a test facility of greatest overall usefulness in a future power reactor development program ... a basic objective of this program was to provide high flux test facilities of ready accessibility.”

This mission has basically not changed during its history (Baugnet et al., 1987). The main design change has been the power upgrade in 1971. During the refurbishment of 2015, the beam tubes, out of use since a long time, have been removed. With the change of the societal and industrial focus from power production to non-power applications, the utilization of the reactor has shifted over the years, but the basic mission to provide a flexible platform for performing irradiations has remained.

Nuclear reactor design

Fuel design

Fuel construction and fabrication

The BR2 driver fuel elements consist of six concentric cylinders (Fig. 2). The fuel meat is currently based on highly enriched Uranium (90–93%). The outer diameter of the standard fuel elements is 8.4 cm; the inner diameter is 2.5 cm, which allows the insertion of irradiation devices inside the fuel elements. Non-standard elements may have less plates (inner fuel ring or two rings removed) or a different outside diameter to be loaded in non-standard channels (20 cm outer diameter elements or six elements with 5.7 cm outer diameter elements were used in 20 cm channels).

The initial fuel design was based on seamless or welded tubes, containing 224 g of ^{235}U as UAl_4 . This fuel design was replaced by a new design, using UAl_x cermet fuel meat. This development was coupled to the power upgrade of the reactor to 100 MW. In a second stage, cermet fuel of the same density, containing burnable absorbers in the fuel meat was introduced in order to prolong the reactor cycle and improve the fuel economy. At this same time, the tube design was replaced by a three-segment bent plate design using stiffeners, so the central aluminum tube could be removed and experimental capsules could be inserted into the center of the fuel elements more easily.

Fig. 2 A standard driver fuel element of the BR2 reactor, consisting of six concentric tubes, formed by three plates, swaged into stiffener plates.

The fuel elements are constructed according to the standard industrial practice of powder metallurgy to prepare the fuel compacts, then rolling and forming the plates and finally swaging the fuel plates into the stiffener plates to form the elements. In the past, extrusion of tubes was also used as a fabrication technique, as well as welding three 120-degree segments into tubes.

Nuclear physics parameters

The availability of irradiation positions inside the driver fuel elements and the flexibility of optimizing the reactor core configuration yields a high variety of possible irradiation conditions. The neutron flux can reach $10^{15} \text{ n cm}^{-2} \text{ s}^{-1}$ thermal flux and $6 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$ fast flux ($E > 0.1 \text{ MeV}$). Typical neutron spectra are given in Fig. 3. The use of absorbing screens to tailor the neutron spectra has been applied mainly for fast reactor fuel experiments (Fig. 4).

The BR2 driver fuel elements are currently used to a burn-up at final discharge of about 55% of the initial fissile metal content. Together with the consumption of the burnable absorbers, this implies a very significant evolution in nuclear physics parameters of the elements during their useful lifetime in the reactor. The effect of the burnable absorbers is twofold:

- The initial loading of the elements with fissile material can be increased without jeopardizing the safety in terms of reactivity for storage or loading of the reactor. The elements with burnable absorber produce a lower k_{eff} in an infinite hexagonal lattice than the initial fuel design with no burnable absorbers.
- As the burn-up of the fuel elements increases, the reactivity of the elements increases. This allows BR2 to use the elements for a significantly longer time in the core of the reactor, as their reactivity increases in the initial stage of life in the reactor.

Path to conversion to LEU

At the initial stage of the Reduced Enrichment for Research and Test Reactors (RERTR) program, it was recognized that the BR2 driver fuel could not be converted to a fuel system based on low enriched uranium (LEU) as it was available at that time. Recently,

Fig. 3 Neutron spectra in the axis of a fuel element (top) and in a 20 cm Be plug (bottom).

Fig. 4 Application of Cd screen to harden the neutron spectrum in a BR2 loaded experiment inside a fuel element.

advances in fuel development and minor redesign of the fuel element have led to two potential fuel systems, suitable for conversion of the BR2 driver fuel.

- Dispersed UMo with a density of 7.5–8 g of uranium per cm^3 . Due to the absorbing nature of molybdenum, this type of fuel requires a higher volume fraction of Uranium in the fuel meat, but due to the higher density of the uranium-molybdenum alloy, this is feasible. The UMo with 7.5 g cm^{-3} uranium has the same equivalent fissile content. The fuel meat volume remains the same in the plate design as in the HEU case. However, due to poor irradiation behavior, this type of fuel could not be qualified to the required extent of power level and burn up requirements for the BR2. A back end solution (i.e. recycling of the material) is not available for this type of fuel. Under Belgian regulation, the availability of a back-end is a requirement.
- Dispersed U_3Si_2 : a higher density than the 4.8 g cm^{-3} which is described in NUREG-1537 is required in order to meet the performance goals for the BR2 reactor. In order to limit the volume fraction of the dispersed phase to less than 50 vol%, the uranium density in the selected fuel system has been limited to $5.3 \text{ g of uranium per cm}^3$. The details of the fuel element design evolution and qualification can be found in reference (Kalcheva et al., 2018).

Core configuration

One of the unique features of the BR2 reactor is that the core configuration is not fixed in the design nor the license. The core consists of a metallic Beryllium matrix, in which 79 irradiation channels are present. There are three types of irradiation channels:

- Standard channels have a diameter of 8.5 cm; 64 channels of this size are present in the matrix. These channels may contain standard fuel elements, control or regulation rods, experiments or a Beryllium plug.
- Large channels with a diameter of 20.3 cm, five in total, of which one is the central channel of the reactor. These channels may also contain experiments or plugs. In standard conditions, Beryllium plugs with either three channels of 8.5 cm diameter or one channel of 8.5 cm, surrounded by six channels of 3.3 cm diameter can be loaded in such 20 cm channels. Plugs with different configuration can be inserted for dedicated experiments. Also, dedicated fuel elements with outer diameter of 20 cm can be loaded in such channels. The number of fuel plates in such elements is optimized according to the required space inside this fuel element to insert an experiment.
- Small channels with a diameter of 5.0 cm are located at the periphery of the core. There are 10 such channels. These channels cannot contain fuel elements nor control rods.

The selection of the core configuration depends on the demand for irradiations, the reactor cycle length and the number and position of the control and regulating rods. The reactor cycle length is typically between 21 and 35 days. Shorter cycles may be performed for dedicated experiments.

The configuration of each cycle needs to fulfill the safety criteria:

- The minimum available anti-reactivity (shutdown margin necessary to keep the reactor subcritical) needs to be above $\$2.00$, in the most unfavorable conditions, including malfunctioning of the most reactive control rod.
- The heat flux on the driver fuel element plates may not exceed 470 W cm^{-2} . This limit is evaluated for the hottest fuel element at the most penalizing position of the shim rods.

Respecting these criteria, the configuration is composed with the following objectives:

- to provide the required flux levels in the different irradiation devices loaded in the reactor core. This is done by selecting the appropriate fuel elements and beryllium plugs, containing the irradiation rigs and surrounding them. The total reactor power can be adjusted as additional degree of freedom, within the limit of the cooling capacity of the primary and secondary cooling loop (125 MW maximum).
- to provide the required cycle length by loading a sufficient amount of uranium; this is done by selecting the appropriate number of fuel elements and their burn-up at the beginning of the cycle.

Reactivity control and safety systems

Scram safety control rods or other shutdown systems

A number of shim-safety rods needs to be present into the core configuration, as required by the technical specifications. These rods are inserted from the top cover of the reactor and have an absorbing element consisting of metallic Hafnium with a length of 94 cm (exceeding the fueled zone by more than 10%). The rods are withdrawn by electromagnetic motors, which are fail safe upon an inadvertent loss of electrical power. Rods are dropped by spring assisted gravity. The absorbing part is connected to a Beryllium follower. A maximum number of eight shim rods can be loaded in a reactor core configuration, with one additional safety rod (extracted during reactor operation, no shim function). Eventually less shim rods can be used (partially replaced by safety rods).

Reactor trips are engaged either by fast electronic interruption of the electromagnet current in the rods drive mechanisms or by opening of relays. The former method is fastest (response time less than 50 ms) and reserved for the nuclear safety instrumentation action and the primary cooling system pressure. The relay SCRAM is actuated by process variables, detection of failure of support systems or experiments.

Regulating rod and control systems

One or two regulating rods can be loaded in the reactor vessel but only one rod can move at a time. Only one rod is required and operational in the regulation control loop. The regulating rod is loaded in a reactor channel where its reactivity worth is less than \$0.48. The regulating rod provides the following functions:

- automatic start-up of the reactor from 1% to 100% power;
- stabilization of the reactor power at a constant level;
- automatic slow or fast set back of the reactor power.

The power regulation system is based on a double loop measurement of neutron flux in the reactor and the relative power change, measured by the ^{16}N in the primary water. The absolute power calibration is done using the thermal balance of the primary cooling loop.

Primary and secondary cooling loops

The reactor core is cooled by demineralized water, flowing at about 10 m s^{-1} along the fuel plates. The inlet water temperature is maintained below 40°C ; the outlet temperature is maintained below 60°C . The inlet pressure in the reactor is $1.2 \times 10^6 \text{ Pa}$ (12 bar), with a pressure drop over the reactor of $3 \times 10^5 \text{ Pa}$ (3 bar) (about $2.1 \times 10^5 \text{ Pa}$ (2.1 bar) pressure drop over the fuel elements). As the reactor channels are fed from a common top water plenum, the pressure drop across all channels needs to be the same. Experiments therefore need to be designed not to create a hydraulic by-pass through the core, which would reduce flow through the fuel elements. The total flow rate depends on the configuration of the core, as fuel elements typically require more flow than plugs or experiments. For a typical configuration, the flow needed to maintain the set pressure drop is around $25.2 \times 10^6 \text{ m}^3\text{s}^{-1}$.

The primary cooling system loop contains four main pumps (three in operation, one in standby) and two shut down pumps which are used when the reactor is not operating. The primary pressure is maintained by an electrical pressurizer, which also serves as degassing unit. The three primary heat exchangers operating in parallel have a total cooling capacity of 125 MW. The heat is transferred to the atmosphere in open cooling towers with forced draft. In order to limit the environmental impact if a sudden rupture in the main heat exchangers would occur, the acceptable contamination level of the primary water is 400 Bq cm^{-3} of ^{131}I . The primary water is continuously purified by resin ion exchange. The pH is maintained typically between 5.5 and 6.5. The residual heat from the BR2 driver fuel can be evacuated either by forced convection (with the main or shutdown primary cooling pumps) or by natural convection if there is a loss of electrical power. In the latter case, the flow will reverse from top-bottom flow to bottom-up flow.

In order to avoid fuel damage, the maximum heat flux on the driver fuel plates has been limited to 470 W cm^{-2} . However, for some experiments, 600 W cm^{-2} can be allowed when the experiments are cooled by the primary water. (600 W cm^{-2} corresponds to the onset of nucleate boiling). This limit only applies in nominal conditions of operation of the primary loop and cooling water gaps which are not smaller than the BR2 driver fuel plate spacing (3 mm water gap between the plates). For similar reasons, experiments inserted inside driver fuel elements may not generate more than 25 W cm^{-2} , 23 s after reactor SCRAM.

Experiment cooling loop

This is a closed loop available as heat sink to experimental devices. The experiment primary cooling loop operates at 1.5×10^6 Pa pressure, with a maximum allowable temperature of 109°C . The flow rate in the primary experiment cooling loop is $3.24 \times 10^5 \text{ m}^3 \text{ s}^{-1}$. The total cooling capacity of this experiment cooling loop is 25 MW; typically, individual experiments can generate up to 5 MW, with the heat transferred to the experiment cooling loop.

Eventually, demineralized water from the primary experiment cooling loop may be fed directly into experiments at low flow rate; this mode is a bleed mode and the water is evacuated towards the liquid radwaste system of BR2 afterwards. Such experimental devices are cooled by the BR2 main coolant loop and the water of the experiment cooling loop only provides a separate environment to the experiment (mainly used to maintain different pressure and temperature than the main loop in the experiment).

In-core experimental capabilities (thimbles, loops, rabbit, etc.)

As pointed out in the section on core design, the BR2 reactor channels can accommodate different types of experimental rigs as shown in Fig. 5. These rigs can either be installed in an entire channel or inside the central cavity of a fuel element (standard fuel element or element with five plates). All channels are accessible from the top of the reactor, so experiments are typically loaded through the reactor pool into the reactor. Experiments can be cooled by the primary water of the BR2, by pool water (in a thimble tube) or by independent cooling loops. For the installation of loops, the five channels of 20 cm diameter and 12 standard channels of 8.5 cm can also be accessed from the sub pile room. This allows for the installation of through loops in the reactor.

Experiments in the BR2 reactor can be loaded in four types of irradiation positions:

- Irradiation positions inside fuel elements: these can be in standard six plate elements (F1) (diameter 2.54 cm) or dedicated five plate elements (F2) (diameter 3.2 cm) for more space. Typically, these positions yield the highest fast flux levels but limited space. The fluxes quoted in the table scale with the power level of the reactor and can vary depending on the position of the element and the burn-up level of the surrounding elements.
- Irradiations in standard channels (S): flux levels will depend on the position of the channel in the reactor (total flux) and the thermal to fast flux ratio will be optimized by the number and burn-up of the surrounding fuel elements. All standard channels have a diameter of 8.4 cm; the flux level generally varies with the distance to the reactor's central flux trap.
- Irradiation in large channels: there are five large channels (H), offering space up to 20 cm in diameter. These channels can contain a single irradiation rig (20 cm), 1–3 standard channels (8.4 cm) or a combination of a standard channel with six small channels (3.3 cm).
- Irradiation in peripheral channels (P; 5.0 cm diameter), located at the edge of the matrix.

The dimensions of the different irradiation channels and typical available flux ranges are given in Table 1.

Fig. 5 Typical core configuration of the BR2, combining the irradiation of production devices and experiments.

Table 1 Nuclear characteristics of the irradiation channels.

Channel type	Thermal flux range ($10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$)	Fast flux range ($10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$) ($E > 1 \text{ MeV}$)	Gamma heating (W/g Al)	Diameter (mm)	Typical number available

^aThe five plate elements are loaded upon experimental request; the amount in the core depends on the number of used/available rigs requiring a five-plate element.

^bThe number of available standard channels depends on the configuration (number of fuel elements, control rods and isotope irradiation facilities loaded).

^cThe 20 cm central flux trap can be configured to hold one 20 cm rig, or one 8.4 cm rig and six 3.3 cm rigs. In the 8.4 cm rig also a fuel element in the central flux trap can be loaded with an irradiation rig inside.

^dThe available peripheral 20 cm channels are configured with three inner 8.4 cm channels in the standard configuration. One channel is reserved for silicon doping.

Loading and unloading of thimble tube experiments can be done during reactor operation. Experiments inserted into the primary water of the BR2 cannot be unloaded during reactor operation (the devices for production of ^{99}Mo by irradiation of uranium targets being an exception).

For unloading experiments to the pool, either the entire experimental capsule can be unloaded or the capsule/loop can be opened in the reactor pool. The reactor loading crane can handle loads up to 360 kg; for larger loads, a polar crane with hoists of 5 tons and 25 tons is available. Materials and rigs can be stored in pools in the reactor building or transferred to the adjacent process building storage canal. On this storage canal, a large hot cell is available for loading and unloading irradiated materials from irradiation rigs. This connection allows flexible and fast handling of irradiated materials. For irradiated fuels, cooling down to remove decay heat may be required before transfer to the hot cell. The storage pools in the reactor building have a separate cooling loop.

Thimble tubes are available in two sizes, one with diameter 3.6 cm (standard size) and one with diameter 7.0 cm (large size). The standard thimble tubes are (amongst others) used to irradiate materials in standard capsules, having an inner diameter of 2.3 cm and a useful inner length of 7.0 cm. In support of irradiation capsules for materials and fuel, a water chemistry control unit is being built to be connected to the primary experiment cooling loop. This unit will provide water with controlled pH (through LiOH addition) and hydrogen content to irradiation capsules for materials and fuel pin irradiation.

Irradiation devices loaded inside the reactor's primary circuit can in general not be unloaded during the reactor cycle (Mo-99 production devices being an exception). Hence, all rigs or baskets loaded inside fuel elements and most other rigs are irradiated for the entire reactor cycle.

Several rig designs are available, which can be recharged with fresh or pre-irradiated specimens. An overview of these rigs is given in [Van Dyck and van den Berghe \(2018\)](#). The main rig types are the following:

- Capsules for material irradiation: un-instrumented capsules can be inserted in the primary water of the BR2 reactor. They can either be loaded in a fuel channel (F1 in [Table 1](#)) or a reflector channel (S or P in [Table 1](#)). The irradiation temperature is not controlled but determined based on the predicted nuclear heating rate and the design of the specimen holder in the capsule. In that way, an engineered gas gap between the specimens in their holder and the capsule wall in contact with the BR2 primary water creates a temperature gradient at constant reactor power to obtain the desired irradiation temperature. Capsules with temperature control are available according to the desired irradiation temperature range, environment and neutron flux. For low neutron flux, capsules with electric heating can be inserted in a thimble tube, loaded in a reflector position (S position). The irradiation temperature is controlled by a combination of variation of electric power to the integrated heaters and water flow in the thimble. For high flux applications and water environment, a boiling water capsule is available, inserted in a fuel element (F2 type channel). This capsule offers temperature control by adjusting the pressure to the desired boiling point and operates from 150 to 350 °C. For higher temperatures, a gas filled capsule in an F1 type channel can be used, controlling the irradiation temperature by variation of the pressure of inert gas in the gap between the specimens and the outer wall of the capsule, cooled by primary BR2 water. Such capsule can operate up to 1000 °C.
- Capsules for fuel irradiation: small fuel samples can be irradiated in capsules with controlled gas gaps in order to achieve fast burn up accumulation at various temperature. The temperature can be measured and is set by engineering the geometrical properties of the fuel holder ([Williams et al., 2019](#)). Light water reactor fuel pins can be irradiated in a pressurized water capsule. This capsule allows to control either irradiation temperature or pressure to the desired set point. The fuel pin is cooled by boiling water, with radial heat evacuation. The heat, produced in the rig is measured on line, so the device can be used for steady state or transient irradiations ([Wéber et al., 2010](#)). Finally, plate type fuel can be irradiated in baskets in the BR2 primary water. This device is frequently used in the development of material test reactor fuel ([Van Berghe et al., 2012](#)).

Conclusions

Today, the BR2 reactor remains one of the highest performing and versatile neutron irradiation platforms available to the international community. It allows the utilization of a number of irradiation devices for providing irradiation services to a wide spectrum of clients, from users of radioisotopes and semiconductors to nuclear material and fuel researchers. Thanks to a long-term vision of SCK CEN, supporting the continuous investment and improvement of the installation, an increased and long-term availability of up to 210 days per year up to 2036 can be supported. The available infrastructure and services on site also allow an integrated service to users, from preparation of irradiation devices up to the post irradiation examination on site and shipment of irradiated materials.

Introduction

Material Test Reactors (MTR) have provided an essential support for nuclear power programs over the last 50 years within the Nuclear Community. However, the large majority of these MTRs are more than 50 years old, leading to the increasing probability of some shutdowns for various reasons (e.g., life-limiting factors, heavy maintenance constraints, possible new regulatory requirement) as one may have seen recently with the permanent shut-down of OSIRIS (Greek: “The King”) in France (2015), JMTR (Japan Materials Testing Reactor) in Japan (2017) and Halden project in Norway (2018). Such a situation is not sustainable in the long term.

On the other hand, when associated with hot laboratories for the post irradiation examinations, MTRs remain key infrastructure facilities for the research area in the field of nuclear fission energy. MTRs address the development and the qualification of materials and fuels under irradiation with sizes and environment conditions prototypical for nuclear power plants in order to optimize and demonstrate safe operations of existing power reactors as well as to support future reactor design:

[☆] Jules Horowitz (1921–1995) was a prominent French scientist who founded the reactor physics division at CEA; this research reactor's name is a tribute to his intense contribution to nuclear physic.

- Nuclear plants will follow a long-term trend driven by the plant life extension and management, reinforcement of the safety, waste and resource management, flexibility and economic improvement.
- In parallel to extending performance and safety for existing and power plants to come, R&D programs are taking place in order to assess and develop new reactor concepts (Generation IV reactors), innovative fuel and materials that meet sustainability purposes.
- In addition, for most nuclear countries, keeping competences alive is a strategic crosscutting issue; developing and operating a new and up-to-date research reactor appears to be an effective way to train a new generation of scientists and engineers.

It is important to note that new facility construction today is much more complicated due to safety and environmental regulations plus the higher costs of labor and materials and, currently, there are only two new high power (above 30 MW) MTR under construction worldwide:

- JHR at CEA Cadarache (France) mainly in support to LWR
- MBIR in RIAR-Dimitrovgrad (Russian Federation) mainly in support of fast spectrum reactors.

JHR at a glance

JHR will offer modern irradiation experimental capabilities to study material & fuel behavior under irradiation (Bignani et al., 2011). JHR will have a flexible experimental infrastructure to meet industrial and public needs related to present and future nuclear power reactors. JHR is designed:

- to provide high thermal and fast neutron fluxes,
- to run highly instrumented experiments,
- to support advanced modelling allowing prediction beyond experimental data points,
- and to operate experimental devices under specific environmental conditions (pressure, temperature, flux, coolant chemistry) typical of light water power reactors (PWRs, BWRs, VVERs), but with some limitations as it is a water research reactor-in support of non-water reactors R&D (sodium cooled fast reactors).

These objectives require representative tests of structural materials and fuel components as well as in-depth investigations with “separate effects” experiments coupled with advanced modelling. For example, the JHR design accommodates improved on-line monitoring capabilities such as a fission product laboratory directly coupled to the experimental fuel sample under irradiation.

As a modern research infrastructure, JHR will contribute to the development of expertise and to the training of the next generation of scientists and operators with a positive impact on nuclear safety, competitiveness, and social acceptance. The JHR is designed mainly to meet these technical and societal objectives. As an associated objective, the JHR will also contribute to secure the production of radioisotopes for medical applications. The following Fig. 1 gives a schematic view of the facility and a photo of the building site as of mid-2020.

JHR, as a future international user facility, is funded and steered by an international consortium gathering industry (Utilities, fuel vendor, reactor designers) and public bodies (R&D centers, Regulator and academic institutions). The generic model of JHR consortium is the following:

- CEA remains the owner and the nuclear operator of the nuclear facility with all liabilities,
- JHR Consortium Members are (for the whole operation life of the reactor) the owners of Guaranteed Access Rights to the experimental capacities in proportion to their financial commitment to the construction and with a proportional voting right in the Consortium Governing Board,
- A member can use totally or partly his access rights for implementing proprietary programs with full property of results and/or for participating to the Joint International Programs open to non-members
- JHR consortium membership is open to new members until completion of the reactor.

CEA is encouraged by the consortium to enlarge JHR membership and, as of mid-2020, the present members list of JHR consortium is the following: CEA (France), EDF (France), AREVA.SA (France), FRAMATOME (France), TECHNICATOME (France), European Commission-JRC, SCK-CEN (Belgium), UJV-NRI (Czech Republic), VTT(Finland), CIEMAT(Spain), Studsvik (Sweden), DAE(India), IAEA (Israel), and NNL (United Kingdom).

JHR general description

This facility is a 100 MWth pool type reactor with a compact core (60 cm fissile length, 70 cm diameter) cooled by a slightly pressurized primary circuit (Coulon et al., 2019). The nuclear facility comprises (Fig. 1) a reactor building with all systems dedicated to the reactor and experimental devices; and an auxiliary building dedicated to tasks in support for reactor and experimental devices operation (hot cells, storage pools, laboratories).

The reactor building consists in pre-constraint concrete with a diameter of 37 m. The nuclear auxiliary building consists in three storage pools for spent fuels, irradiated experimental devices and in four hot cells for preparation, conditioning of experiments and

Fig. 1 Jules Horowitz Reactor (JHR) schematic view and photo as of mid-2020. Courtesy CEA.

non-destructive examinations on irradiated samples. A transfer channel between the reactor building and the nuclear auxiliary building allows the underwater transfer of spent fuels and experimental devices between the two buildings. In support to the nuclear island, additional ancillary facilities include the following:

- 1 support building for cooling system
- 1 support building for the fluids and ventilation facilities
- 2 emergency diesel generator buildings
- 1 building for assembly and test of experimental devices before entering the nuclear island ("cold workshop").

The design of the core and Beryllium reflector provides various irradiation locations and cavities; the core consists of 37 silicide fuel elements (U_3Si_2 -cylindrical shape) with several control and pilot rods made of Hafnium (see Fig. 2 below).

The reactor facility is designed to operate 20 experiments simultaneously in the various testing locations:

- Located in the core (7 of small diameter; 3 of large diameter) which are characterized by a high fast neutron flux ($5.5 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$ with energy above 1 MeV corresponding to 16 dpa (displacements per atom)/year).
- Located in the beryllium reflector zone surrounding the core, (about 20, most of them of 10 cm diameter), with a high thermal neutron flux (up to $5.5 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$). Material experiments requiring a low radiation exposure rate (such as the reactor pressure vessel steel) will be installed in the reflector because of the low fast neutron flux corresponding to about 0.1 dpa/y.

Fig. 2 JHR cross-section with central reactor core surrounded by reflector and sketch of fuel element. Courtesy CEA.

Fig. 3 Neutron flux normalised per unit of lethargy $[\text{Log}(E_{\text{ref}}/E)]$ versus Neutron Energy for JHR core. Courtesy CEA.

- Four to six water channels (depending on the core configuration) through the reflector are equipped with displacement devices to accurately control the distance to the core and therefore the irradiation flux (e.g., for an accurate stable power, for power ramps, or for power cycling).

As shown in the Fig. 3, the JHR design allows both high thermal neutron flux and fast neutron flux allowing high performance experiments of fuel and structural material.

The JHR experimental capacity will also include non-destructive examination (NDE) benches: a coupled gamma scanning and X-ray tomography bench located in the reactor pool, a similar bench located in the storage pool of the Nuclear Auxiliary Building (and a neutron imaging system located in the reactor pool).

JHR construction update status as of 2020

The civil work of the reactor was completed in spring 2018 and the project is now in a new phase focused on “components integration”. Engineering studies were contracted to Technicatome, which supervises the construction site, and which is also in charge of providing key reactor components. More than 20 other suppliers in the fields of civil works, mechanics, heating, ventilation, air-conditioning, and electric components contribute to the construction of the facility. In March 2020, a new organization was put in place consisting of CEA, Technicatome and Framatome in an integrated team for enhancing this second phase of mechanical erection and completion of the reactor.

JHR safety design

As a new construction facility, JHR incorporates safety analysis right from the design phase, based on a modern reference system and methodologies. It can be linked to those used in contemporary projects such as the current next generation NPPs under construction, but adapted to the characteristics and situation of a research reactor project.

Following the Fukushima-Daichi Accident (March 2011), the French Regulator (Autorité de Sûreté Nucléaire-ASN) also asked CEA to perform complementary safety assessments to meet objectives under extreme situations exceeding licensing basis (with focus on “cliff-edge” effect prevention; that is, avoiding an incidental scenario leading to several others) (Bignan et al., 2011). The complementary safety assessments confirmed the sound design bases of the newly designed JHR under construction. A few selected needs for extra equipment were also identified, and, as an answer to French nuclear regulatory requirements, CEA proposed a set of “hardened core” measures including for example:

- An ultimate recirculation pump on the reactor main cooling circuit.
- Pipes and valves for ultimate pool water supply from outside the containment building
- Ultimate valve actuation on some ventilation lines.
- Dedicated sensors to independently measure pressure and radio-activity level in the containment building.
- Specific ultimate power set for the above-mentioned equipment's.

Developing a modern experimental capacity

JHR is designed as a high performance MTR (thermal power up to 100 MW) with the capacity to perform about 20 experiments at the same time. Characteristics (at full 100 MW capacity) are as follows:

- thermal neutrons flux in reflector: up to $5.5 \text{ E14 neutrons cm}^{-2} \text{ s}^{-1}$
- fast neutron flux in the core: up to $5.5 \text{ E14 neutrons cm}^{-2} \text{ s}^{-1}$ for $E > 1 \text{ MeV}$ and/or up to
- $\text{E15 neutrons cm}^{-2} \text{ s}^{-1}$ for $E > 0.1 \text{ MeV}$
- material radiation damage: up to 16 displacements per atom (dpa) per year
- six displacement systems to adjust fissile power and perform power transients
- power transients for fuel limit to clad failure studies: linear power up to 600 W cm^{-1} .

At nominal operation JHR is to operate with 8 cycles a year (representing about 180 EFPD-Equivalent Full Power Days).

CEA with its partners is preparing the first experimental capacities by developing some modern experimental devices for fuel and material behavior studies under irradiation such as the following (Gonnier et al., 2018; Young, 2021):

- the MADISON™ loop for fuel investigation under normal condition (evolution of the fuel micro structure, clad corrosion, fission gas releases ...),
- the ADELINÉ™ loop for power transient studies (ramps) allowing clad failure for up-to-limit situations,
- the LORELEI™ loop for safety LOCA (Loss Of Coolant Accident) studies for accidental scenarios,
- the MICA™ capsules for material investigation under high fast neutron flux and high dpa rate,
- the MELODIE™ device for on-line bi-axial constraint analysis (analysis in both axial and radial directions) on material,
- the OCCITANE™ device for RPV (Reactor Pressure Steel) degradation studies,
- the CLOE™ loop for material corrosion studies.

The following Figs. 4 and 5 indicate the location of some experimental devices within JHR core and reflector.

Compared to the existing experimental capacities worldwide, a great effort is ongoing to improve the performance of such loops and to develop new devices with innovative concepts by

- better monitoring and follow-up of the irradiation conditions,
- having much more on-line instrumentation to measure key parameters (e.g., fast and thermal neutron fluxes, gamma heating, temperature, fission gas release for fuel investigation, and material elongation),
- having modern well-equipped post-irradiation examinations either directly within JHR nuclear building (for non-destructive assay) or in Cadarache Hot Laboratory (for non-destructive and destructive examinations) or in consortium members hot laboratories.

Radioisotopes production

Molybdenum 99 production

The JHR objectives for this radioisotope are to be able to produce an annual volume of 25% of European needs on an average basis and up to 50% of European needs in peak production. For this, production must be flexible according to customer's needs.

Irradiation capacity for Moly production will be flexible according to customer's orders and may be extended for limited periods as following:

- Weekly maximum capacity: up to $4800 \text{ }^{99}\text{Mo Curies (Ci)}/6\text{-days week}$
- Yearly maximum capacity: up to $115,200 \text{ }^{99}\text{Mo Ci/year}$.

Fig. 4 Location of several experimental devices in JHR core and reflector.

Fig. 5 Location of several experimental devices in JHR core and reflector.

The Moly facility has been designed for this production capacity, while integrating safety and operational constraints. From the beginning, the Moly irradiation devices will use Low Enriched Uranium (LEU) targets.

The facility is composed of two main parts:

- the in-pile part in the reactor pool, which includes four Moly device vessels with the target holder, a movable system, underwater lines up to the piping penetrations and two safety pumps;
- the out-of-pile part is composed of the piping penetrations allowing the junction between the in-pile cooling circuit and out-of-pile cooling circuit, equipment for instrumentation and control system (I & C) and power supply.

Fig. 6 Implementation of the Moly devices in the JHR reflector.

In the JHR beryllium reflector, a reflector sector has been designed to accommodate the four Moly devices and their movable system (Fig. 6 below), in order to provide a large production capacity with the greatest flexibility.

Other radioisotopes

Other isotopes, such as ^{131}I and ^{133}Xe , are produced in the uranium targets through fission reactions and could be extracted. Such radioisotopes are important for nuclear medicine applications. In parallel and in accordance with customer needs, feasibility studies could be performed in order to develop the production equipment for radioisotopes production based on neutron capture reactions. Many irradiation positions are located in the Beryllium reflector. The potential thermal neutron fluxes would allow JHR to produce by neutron activation ^{90}Y , ^{153}Sm , ^{166}Ho , ^{169}Er , ^{177}Lu , ^{186}Re , ^{192}Ir , ^{103}Pd , and ^{125}I (as examples) for medical purpose. Production of radioisotope in fast and epithermal neutron fluxes could also be investigated. Finally, JHR could also produce radioisotopes such as ^{192}Ir , ^{60}Co , ^{75}Se and ^{169}Yb for industrial purposes. Due to JHR neutrons fluxes, high production rates are expected.

JHR as an international user-facility through international joint programs and/or academic support

Parallel to the completion of the reactor construction, the establishment of an international community around JHR is continuing. This is important because, as already indicated, building and gathering a strong international community in support of MTR experiments is a key-issue for R&D in the nuclear energy field.

According to the consortium agreement, JHR will become a user reactor at an international level with multinational projects and proprietary experiments. As anticipated preparatory actions, the JHR consortium has set-up a yearly scientific seminar and three working groups (Fuel, Material and Technology) to identify R&D topics of common interest and to prepare the first international joint programs addressing fuel and material issues that are key for operating plants and future NPP (mainly focused on LWR).

This latest seminar (the 10th seminar was held in April 2019) gathered about 100 participants and is a unique opportunity for the future end users to share and discuss progress on the latest developments on JHR experimental capacities. The main outputs of such seminars are to identify scientific needs leading to proposal of future R&D programs with precise requirements regarding the management of irradiation conditions and the performances of the instrumentation of the experimental devices. Current planning focus is on the mastering and follow-up of the irradiation conditions in terms of local neutron flux and spectrum, temperature homogeneity and thermal gradients, with the possibility to un/re/load irradiated materials in the JHR experimental devices.

The experimental priorities are directed toward Generation II-III nuclear power systems with needs related to:

- LWR fuel element performance under nominal operation (fuel rod, cladding, fuel assembly) for various new fuels (UO₂ with additives, burnable absorbers) and clad candidates, including Enhanced Accident Tolerant Fuels, for various chemical environments and various power conditions (power cycling, load following and extended operation at reduced power level).
- LWR fuel testing in normal operational conditions: power ramps (crack initiation and propagation, clad integrity thresholds, pellet-cladding chemical interaction, fission products release and radiological source-terms), power to melt, and fuel assembly lift-off phenomenon.
- LWR fuel behavior under accident conditions such as LOCA-type conditions (clad ballooning and hydriding, fuel fragmentation, pulverization and ejection, grid-spacer effects, radioactive source term, and fuel assembly geometry after quenching).

For the LWR fuel assemblies and core structures, special attention is given to behavior of guide tubes and grid spacers: grid-spring interaction, guide tubes axial creep, and effect of rod bowing. For the control rods and burnable absorbers: thermal-mechanical and

geometrical evolutions and neutron absorber consumption (Young, 2021). Specific irradiation testing needs related to core materials:

- For the cladding: Mechanical behavior (creep test) with on-line biaxial (axial and radial) control (stress and strain), effect of environment on mechanical behavior, effect of dose accumulation on cladding (microstructure, hardening, embrittlement, creep for Gen II/III, and microstructure, swelling, embrittlement, creep for Gen IV).
- For the Reactor Pressure Vessel (RPV): Dose accumulation with the Irradiation effect on the microstructure and mechanical properties.
- For core internals: dose accumulation and environment effect on mechanical behavior.
- For Absorbers: Dose accumulation, effect of irradiation on the microstructure.

The JHR scientific team at Cadarache is already welcoming scientists, engineers (called *Secondees*) from various organizations and institutes, who are integrated within the JHR team for a limited period of time (typically 1 year) for various projects such as physics studies for the development of the experimental devices (neutron physics and thermal-hydraulics) and for support to future operations (e.g., safety analyses).

This Secondment program is important for countries willing to invest in nuclear technology as it helps to create and sustain key technical competences.

Conclusion

JHR will be a major international research infrastructure regarding fuel and material behavior under neutron irradiation; it will perform R&D programs for the optimization of the present generation of Nuclear Power Plants (NPPs) but also support the next generation of NPPs.

The JHR construction will continue with completion expected in accordance with project plans to start normal operations by the second part of this decade. Beyond current construction activity, the facility, especially regarding the experimental capacity, is already open (and will be more and more so in the future) to international collaboration: As some examples of current collaborations are the output of the various working groups who identified R&D topics of common interest such as:

- LWR fuel testing up to limits and in incidental conditions (fuel element thermal-mechanical behavior, fuel-cladding chemical interaction, fission gas and volatile fission products release and associated source term, transient swelling)
- Dose accumulation in low-alloyed steels for reactor pressure vessel and new cladding studies for accident tolerance.

Typically, such R&D programs could be managed through international joint programs open to non-Members of the JHR consortium. To summarize, JHR prepares to be a key research and development infrastructure in the European and International nuclear materials research areas to support the use of nuclear energy during this century.

Introduction

The nuclear era in Germany started on June 11, 1956 when Prof. Heinz Maier-Leibnitz of the Technische Hochschule München—now the Technical University of Munich—was empowered by the Bavarian Minister-President to purchase a swimming pool reactor in the United States of America. This research reactor, called Forschungsreaktor München (FRM), was built in Garching, at that time a small village close to Munich, and taken into operation at a power of 1 MW on October 31, 1957. During the next decades it was upgraded stepwise to a power of 4 MW and became the starting point of many important applications and developments in neutron physics, e.g. neutron guides, ultra-cold neutrons, high resolution spectroscopy, gravity spectrometry using neutrons, neutron irradiations at liquid He temperature, hadron therapy of tumors by fast neutrons, etc. Last not least it was the nucleus of the present large university campus in Garching, populated every day by thousands of students and employees.

With the success of new very intense neutron sources in the United States and Europe, it turned out that the FRM did not meet the requirements for a modern research reactor anymore. Consequently, in 1993 the decision was taken by the Bavarian government to replace the Atomic Egg, as FRM is commonly called, by a high performance neutron source on the same site. The basic design feature of the Forschungsneutronenquelle Heinz Maier-Leibnitz (FRM II), how this new reactor is called, is its single cylindrical compact fuel element providing a thermal neutron flux density of up to $8 \times 10^{14} \text{ cm}^{-2} \text{ s}^{-1}$ (unperturbed) at a moderate thermal power of 20 MW. Its first criticality was achieved on March 2, 2004 and its specified normal operation for scientific users and interested commercial parties started in May 2005 (Schreckenbach and Gerstenberg, 2005). The present external appearance of the reactor site at the Campus in Garching is shown in Fig. 1. For actual information see FRM II homepage.

The dedicated mission of the FRM II is to provide neutrons for all kinds of scientific, industrial and medical applications. For this purpose, it is equipped with 11 beam-tubes and 5 irradiation facilities. In addition to the use of thermal neutrons a cold and a hot neutron source operated at $T = 24 \text{ K}$ and $T > 2200 \text{ K}$ respectively are available to provide the desired neutron spectrum for any kind of beam tube experiment. Further, a setup of two fuel plates located at the edge of the moderator tank “converts” thermal neutrons into an intense beam of fission neutrons ($2.3 \times 10^8 \text{ n}_f \text{ cm}^{-2} \text{ s}^{-1}$) in a narrow energy range around 2 MeV. Moreover, the FRM II is equipped with the worldwide most intense source for thermal positrons ($10^9 \text{ e}^+ \text{ s}^{-1}$) being generated in a beam-tube after thermal n-capture in Cd and subsequent pair-production from high energy gamma quanta. Finally, the installation of an ultra-cold neutron source in a beam tube crossing the moderator tank is in progress.

As of today about 30 beam-tube instruments are in operation at the FRM II, built and maintained by skilled scientists from TUM, the Helmholtz centers Forschungszentrum Jülich and Geesthacht, the Max Planck Society and nine other German universities. Nineteen of these instruments are fed by the cold source, clearly indicating the dominant interest of today's neutron science on long wavelength neutrons. Since 2011 the scientific exploitation of the neutron source happens under the umbrella of the Heinz Maier-Leibnitz Zentrum (MLZ) (Petry, 2019). Actual information is presented on the MLZ homepage. Twice a year measuring proposals are reviewed by a committee of independent international experts. Measuring time at MLZ is allocated solely based on scientific merit. Often, however, the applicants are suffering from the overbooking of the requested instrument by a factor 2–3.

Although the FRM II has clearly been optimized by its design to provide excellent conditions for beam-tube experiments using cold, thermal, hot and fission neutrons there was a consent already during the planning phase that it has to be made available for industrial, technical and medical applications as well. Consequently, commercial companies are using the FRM II as a service provider for the production of radioisotopes or the neutron transmutation doping of Si. In particular, the demand for radioisotopes to be used in nuclear medicine has increased considerably during the last few years. Among other considerations, this development led to the decision to launch a licensing procedure for the production of $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$. This facility is supposed to contribute considerably to the growing European needs for $^{99\text{m}}\text{Tc}$ in the near future.

Fig. 2 View of the FRM II compact fuel element from different perspectives. FRM II/TUM

Nuclear reactor design

The entire reactor core of the FRM II consists of a single very compact fuel element with a maximum outer diameter of 23.7 cm and an active length of 70.0 cm. It contains approximately 8 kg of uranium in the form of U_3Si_2 grains embedded in an Al matrix with a maximum uranium density of 3 gU/cm^3 (see Fig. 2). Like other high performance research reactors, the FRM II is fueled with highly enriched uranium at a degree of enrichment of $>90\%$ in U-235. Each fuel assembly is built up of 113 involute-shaped fuel plates that are clamped between two concentric tubes made from AlMg3 with diameters of $\varnothing_i = 11.8 \text{ cm}$ and $\varnothing_o = 23.7 \text{ cm}$. This geometry guarantees the cooling slits between two adjacent plates to be of equal width over the entire diameter of the fuel assembly. The fuel assemblies are manufactured by the company FRAMATOME-CERCA in France.

The fuel element sits in a light water cooled central channel, which separates the light water from the surrounding heavy water being kept in a moderator tank with height and diameter of equally 2.5 m. Due to the compactness of the fuel element the moderation of the neutrons takes place mainly in the surrounding moderator. This setup makes it necessary to reduce the fuel density in the outer part of the fuel element from 3 to 1.5 g cm^{-3} in order to avoid unacceptable power peaks at its outer surface. On the other hand, due to the same effect the maximum of the thermal neutron flux density shows up some 12 cm outside the core region in the

moderator tank. This feature provides the important advantage that major experimental installations like the cold and the hot neutron source may be installed right in the maximum of the neutron flux density.

Originally, the lifetime of a fuel element in FRM II was 52 full power days (1040 MWd). Fortunately, however, extensive irradiation experiments for the certification of the fuel had been carried out already during the project phase. Their results covered the safe operation of the fuel for a higher burn-up. Consequently, taking advantage of the experience from the first 12 reactor cycles and after evaluating further important parameters like e.g. the efficiency of the control rod at the end of cycle, the maximum burn-up was extended to 1200 MWd or 60 full power days. Ideally, the operational schedule of the FRM II consists of four reactor-cycles per year of equally 60 days in a row.

As mentioned above each reactor-cycle starts with the installation of a fresh fuel element. Consequently, an external neutron source is required to start the reactor. For this purpose, the FRM II is equipped with a primary source based on the spontaneous fission of ^{252}Cf . Since, however, the half-life of ^{252}Cf is 2.65 years only and an exchange of the ^{252}Cf source is expensive and technically challenging a secondary starting source has been installed that uses the photo neutrons being emitted by Be under intense gamma radiation. In more detail: The secondary neutron source consists of 55 compressed pellets containing an equal volume of Sb and Be. The source has a total length of 825 mm and is installed in the moderator tank in a distance of 340 mm from the center of the fuel element. During reactor operation the stack of Sb/Be-pellets is irradiated by about $10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$ and the resulting activation product ^{124}Sb ($T_{1/2} = 60.2$ days) provides the necessary intense gamma radiation to induce the emission of photo neutrons from the Be.

The reactor FRM II is equipped with a single control rod dedicated to regulate the reactor power and to compensate changes in reactivity due to increasing burn-up or variations in the concentration of fission products acting as neutron poisons. In addition, the control rod system is one out of two independent systems that allow to shut down the reactor and to keep the fuel assembly permanently subcritical at any time. Because of their crucial importance, both shutdown systems are implemented in the reactor safety instrumentation and its control and communication system.

The control rod system consists of three major components: drive, connecting rods and the control rod itself, which uses Hf as neutron absorber. During standard reactor operation the control rod is driven with a velocity of approximately 0.08 mm s^{-1} within the inner tube of the fuel assembly in order to balance the reactor power. In case of serious interferences or emergency the control rod drops and the reactor is shut down.

Formally, the control rod is the secondary shut down system of the reactor FRM II. The primary shut down system consists of five independent units being installed on a common radius on top of the heavy water moderator tank. An individual casing protects each of them against contact with the light pool water. Like the control rod, the absorbers of the shutdown-rods are tubes made from Hf. During reactor operation, all shutdown rods are held in their top position by electromagnetic coils. In this position they are dipped into the moderator tank above the fuel element. In case, a relevant signal from the reactor safety instrumentation initiates a SCRAM the holding current of the magnetic coil is interrupted. In this case, stretched springs assisted by gravity accelerate the shutdown rods into their lowest position. In parallel, also the control rod drops into its lowest position. No need to say, of course, that independently of each other the control rod as well as the shutdown rods provide sufficient reduction in reactivity to shut down the reactor reliably and keep it permanently in a subcritical state. Fig. 3 shows schematically a vertical cut through the FRM II indicating main components required for reactor operation.

As a whole, the cooling system of the FRM II consists of three independent circuits safely separated by heat exchangers. The fuel element is cooled by pumping light water at a rate of 300 kg/s through the slits between the fuel plates. Consequently, at nominal reactor power of 20 MW the temperature increase of the cooling water is limited to only 15°C , i.e. from $\approx 35^\circ\text{C}$ to $\approx 50^\circ\text{C}$ between the inlet and the outlet of the fuel assembly. Four primary cooling pumps are necessary to provide the cooling stream. By means of two heat exchangers the nuclear heat is transferred to a secondary cooling circuit acting mainly as a barrier against the possible leakage of contamination into the environment. Finally, a tertiary cooling circuit is transferring the heat to a small cooling tower where it is released to the air.

In case of the unavailability of the standard cooling system the FRM II is relying on a threefold emergency cooling system. Its main components are three identical pumps for the removal of residual heat mounted in the storage pool. After shut down of the reactor in an emergency case each of them is independently capable to provide sufficient cooling to avoid any damage by overheating the fuel assembly. The pumps are battery-buffered in order to allow their operation for at least 3 h. After that period two emergency check valves open automatically due to gravity and the further cooling is driven by the thermosiphon effect. For this purpose, the sieve, a deep lying pipe section of the primary cooling circuit, is intentionally perforated. This construction allows pool water to be sucked through the fuel element due to its residual heat and to be returned into the pool through the check valves. The volume of light water in the reactor pool amounts to about 700 m^3 and is by far enough to provide sufficient cooling after an unintended shutdown for the fuel assembly in the core as well as for all of the in maximum 50 spent fuel assemblies in the pond for any necessary timeline.

A schematic of the FRM II cooling circuits is given in Fig. 4. Further, Fig. 5 provides a view to the reactor hall.

Experimental support systems

The compact core of the reactor with its surrounding heavy water moderator creates a source term of thermal neutrons with a shape of a hollow cylinder where the maximum thermal flux is some 12 cm away from the outer side of the central channel. This design

Fig. 3 Schematic vertical cut through the FRM II reactor indicating major technical components and scientific support systems. FRM II/TUM

provides an ideal geometry for the extraction of neutrons by beam tubes and the installation of spectrum shifters in an optimum position. Further, all beam tubes extracting thermal neutrons are oriented tangentially with respect to the cylindrical source term, thus giving no direct view to leaking fast neutrons towards the beam ports outside the primary concrete shielding. This is one important measure to suppress background from fast neutrons. Like any light microscope neutron instrumentation does not so much ask for intensity, but for brilliance, i.e. neutrons per cm^2 , s, rad and $(\Delta\lambda/\lambda)$. One important measure to achieve this is shifting the neutron spectrum already at the source to the wavelength range needed for a particular instrument or experiment. At FRM II neutrons are shifted to cold (24 K), thermal (60 °C), hot (2000 °C), to fission spectrum (2 MeV), in near future to ultra-cold (mK) and even “converted” to positrons. Eleven beam tubes are available to extract all these particle beams.

The by far most important experimental installation in the moderator tank is the Cold Neutron Source (CNS). Its major component is the moderator chamber located in a distance of 400 mm from the center of the fuel element right in the maximum of the neutron flux density. During cold operation, it contains about 12 l of liquid deuterium at a temperature of ≈ 24 K. A He refrigeration device provides the required cooling power of about 7 kW at 20 MW reactor power. It feeds the cold part of a He/D₂ heat exchanger at a temperature of ≈ 19 K. The deuterium is liquefied in the heat exchanger and rinses down into the moderator chamber where it evaporates again due to the nuclear heat. Finally, by means of the thermosiphon effect the deuterium gas is

Fig. 4 Scheme of the three independent cooling circuits of the FRM II. FRM II/TUM

Fig. 5 View into the FRM II reactor hall. Bernhard Ludewig

led back to the heat exchanger for re-liquefaction. Important out of pile components of the CNS are the He-refrigerator with its compressor, a buffer tank and hydride storage tank to preserve the deuterium during maintenance periods of the reactor when the CNS is heated up. The CNS feeds three beam-tubes and 19 scientific instruments in the neutron guide halls and experimental

hall of the FRM II. Its spectrum is slightly undermoderated with the advantage of providing a broad wavelength spectrum from about $1.8 \text{ \AA}$ to $> 10 \text{ \AA}$. It is important to note that in order to prevent the CNS from thermal damage it must be in operation before the start of the reactor, i.e. malfunction of the cold source automatically triggers an unavailability of the reactor (Müller et al., 2005).

The second spectrum shifter in the FRM II moderator tank is the Hot Neutron Source (HNS). It is dedicated to the provision of short wavelength neutrons in a wavelength range of $0.3\text{--}1 \text{ \AA}$ mainly for the structural investigations in condensed matter samples. As only a small fraction of those neutrons is present in the thermal spectrum a hot moderator is required for their up-moderation. At the FRM II this hot moderator consists of a cylindrical graphite block ($\varnothing = 200 \text{ mm}$; $h = 300 \text{ mm}$) with a weight of about 14 kg . It is contained in a double-walled zircaloy container. The inner volume of this container houses the carbon block being held in position by carbon felt with a low heat conductivity and kept under an inert gas atmosphere at low pressure. In contrast, the volume between the zircaloy walls of the container is kept under about 3 bar He atmosphere in order to guarantee the detection of a possible leak in one of the walls in a timely manner. During reactor operation the carbon block heats up by the nuclear radiation from the reactor core to a value of approximately 2200 K . The temperature within the HNS is measured using a thermometer based on the thermal noise of a carbon resistor. In addition, 36 thermocouples are connected to the zircaloy container in order to supervise its temperature and, as a by-product, indirectly the correct position of the carbon block within the container. The HNS feeds hot neutrons into one beam tube, which supplies two single crystal diffractometers in the experimental hall of the FRM II. The different neutron spectra provided by the CNS, the HNS with respect to the thermal neutron spectrum are shown in Fig. 6 (Müller et al., 2005).

In order to obtain a high intensity neutron beam with an unmoderated fission spectrum, an arrangement of two fuel plates containing in total about 540 g of highly enriched uranium, the converter facility, is inserted as a secondary source in front of one beam tube. Slow neutrons from the moderator tank interact with the uranium in those fuel plates and generate fission neutrons for medical and technical purposes. Without moderation, the neutrons are led through a horizontal beam tube into a room dedicated to the treatment of cancer by direct irradiation with fast neutrons (Wagner et al., 2008). Supplementary, the converter facility can also be used for the radiography and tomography of technical objects using fast neutrons. Furthermore, the converter plates may be lifted out of their position in front of the beam tube. In this operational mode the conversion to fission neutrons does not happen and the beam is used for radiography and tomography with thermal neutrons.

In addition to neutrons FRM II provides the world's most intense permanent source for positrons. The high intensity beam of positrons is generated by pair production from absorbed high-energy gamma-rays. This source is positioned in the cusp of an inclined beam tube, where the required gamma-rays are produced by the absorption of neutrons in an isotopically enriched cadmium layer. The pair-conversion itself occurs in proximate platinum foils (see Fig. 7). The positrons are extracted by means of electric and magnetic fields and guided to several experimental stations attached to the positron beam facility named NEPOMUC (Hugenschmidt et al., 2012). Low mass and adjustable kinetic energy makes the positron a probe perfectly suited to solid state research. As the anti-matter particle of the electron, positrons annihilate electrons with a characteristic lifetime. The emerging annihilation radiation provides detailed information of the local surroundings at the annihilation site. As an example, the positron life

Fig. 6 Comparison of the neutron spectra in beam tubes fed by a thermal neutron source, the cold neutron source and the hot neutron of the FRM II reactor. FRM II/TUM

time is slightly larger in vacancy-like defects than in the unperturbed crystal lattice. In this way, vacancy concentrations as low as 10^{-7} can be detected.

Besides the installations for neutron scattering the FRM II is also equipped with a couple of irradiation facilities. They all have in common that they are installed in light water filled thimbles reaching down from the reactor floor into the moderator tank. The biggest of those installations is the silicon doping facility. Si ingots with a diameter between 125 mm to 200 mm are moved semi-automatically from a loading station into the irradiation position being located in a vertical thimble in the moderator tank. In order to achieve uniform neutron irradiation, an indispensable prerequisite of successful transmutation doping of Si, the ingots are rotated around their central axis during neutron exposure at a rate of typically 5 turns/min. In addition, the irradiation position is equipped with a properly designed flux screen to guarantee the required axial homogeneity of the doping profile. Furthermore, the irradiation position follows the vertical shift of the flux profile with increasing burn-up of the fuel assembly. By accurate adjustment of the exposure time a resistivity between 30 Ωcm and 1200 Ωcm can be achieved with a deviation of less than 5% from target. It is noteworthy as well that the very well thermalized neutron spectrum containing only a low proportion of fast neutrons helps to avoid an undesirable high amount of extended lattice defects within the Si. Of course, the FRM II is also equipped with all necessary tools for the cleaning and release of the irradiated ingots required for the delivery to customers outside the nuclear business (Gerstenberg et al., 2009).

At the FRM II two different rabbit irradiation systems serve not only the production of radioisotopes but also the activation of samples for various topics like e.g. neutron activation analysis or the supply of small sources for education and training. The so-called capsule irradiation facility is used for long-term irradiations at a thermal neutron flux density of approximately $10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$. During irradiation the sample is typically sealed twice in a quartz ampoule and in addition in an Al-capsule with a welded lid in order to avoid its contact with pool water. After insertion into the facility the capsule is led automatically into the irradiation position by a stream of pool water for a pre-determined irradiation time. After completion of the irradiation it is returned the same way into a position dedicated to allow the decay of short lived isotopes. For further processing the capsule irradiation facility is connected under water with the hot cell where the irradiation capsules are opened and the samples are packaged according to the requirements of the regulations for the transport of radioactive goods on public roads. A high demand for this type of irradiation service is presently coming from customers of the radiopharmaceutical industry in particular companies interested in the production of ^{177}Lu (Gerstenberg et al., 2013).

The second rabbit irradiation system at FRM II is a standard pneumatic dispatch using CO_2 as process and transport gas. The samples are contained in individually labelled polyethylene capsules foreseen for single use. The facility provides six individual irradiation channels exhibiting thermal neutron flux densities between $3 \times 10^{12} \text{ cm}^{-2} \text{ s}^{-1}$ and $5 \times 10^{13} \text{ cm}^{-2} \text{ s}^{-1}$. A typical

application is the supply of samples for neutron activation analysis. For this purpose, the facility is connected directly with the neighboring Institute for Radiochemistry (Lin et al., 2006). On the other hand, the facility is used for production of isotopes as well, e.g. the activation of ^{166}Ho dedicated to the treatment of liver cancer.

Guiding neutrons to the instruments

The MLZ makes extensive use of modern neutron guides to transport and distribute the neutrons over large distances in the Experimental Hall, situated around the primary reactor block, as well as in the Neutron Guide Halls West and East. Radiation resistant metallic neutron guides start neutron extraction already within the primary shielding of the reactor block. From the beam ports at the outside of the primary shielding onwards coated glass guides continue neutron transportation to the instruments. Adapted to the needs of the instruments with respect to wavelength distribution and angular dispersion the guide elements are coated with ^{58}Ni or supermirror coatings with m values up to 3.0; on focusing sections up to $m = 3.6$. The value of m refers to the increase of the angle of total reflection for a given supermirror with respect to the angle of total reflection for elemental Ni. For example $m = 2$ means a fourfold increase in transported neutrons compared to an elemental Ni coated guide. Of course, according to the Liouville theorem increase in m goes with a similar increase in divergence. Because the measurable signal, i.e. the ratio of peak-to-background is the interesting quantity in an experiment and not alone intensity in the peak, stringent background suppression is priority in the lay-out of the guide systems at MLZ. For that purpose:

- (i) All guides are curved in order to have a cut-off for undesired short wavelength neutrons. For some instruments in Guide Hall West even S-shaped curvatures are used to strictly suppress fast neutrons running along the outer side of a one-sided curved guide.
- (ii) The value of m is chosen in a way, that only the needed divergence is delivered to the particular instrument.

Further, extreme attention is paid to shielding of the neutron guides.

Cold neutron guides: Beam tube SR-1 facing the cold neutron source delivers the neutron beams for the entire Neutron Guide Hall West. The in-pile unit of SR-1 consists of a mirror box with $m = 2.2$ supermirror coating on Al plates and a dividing section of 2.1 m length, where the beam is divided into the six principal neutron guides. Each of those is further split in order to serve a maximum number of instruments, especially with terminal positions. Altogether 15 instruments are served out of SR-1. Two other beam ports looking in the experimental hall face the cold source. SR-2 serves the three-axes spectrometer PANDA. SR-4 serves the imaging station ANTARES and in the near future the nuclear and particle physics beam line MEPHISTO in the Neutron Guide Hall East.

Thermal neutron guides: Beam tubes SR-8a and SR-8b are equipped with supermirror guides with coatings up to $m = 3$. At SR-5b a polarizing supermirror bender provides the instrument TRISP with polarized neutrons. In the near future, elliptical focusing thermal guides will provide neutron beams for the instruments in the Neutron Guide Hall East.

The entire setup of neutron guides and connected instruments is shown in Fig. 8 and described in Petry and Brückel (2015). The experimental stations in the Neutron Guide Hall East are presently still under construction. In addition, Fig. 9 gives an impression on the occupancy level in the experimental hall of the FRM II.

Instrument classes

As already mentioned, instruments at MLZ are designed to have highest brilliance and lowest background. A broad range of techniques is used for defining the incoming wavelength and analyzing the scattered wavelength such as double focusing Bragg crystals, time-of-flight, wavelength selectors, classical as well as resonant spin-echo. Most instruments have the option to polarize the incoming beam and to analyze the polarization of the scattered beam. As polarizing devices Heusler crystals, polarizing supermirrors and He absorption filters are in use. All instruments belong to the best of their class, some of them are unique or world champion.

Large angle diffraction: Large angle diffraction is the working horse of any decent neutron source. Questions like “Where are the atoms?” and “What is their magnetic moment?” are tackled. The diffraction instruments include the high resolution powder diffractometer SPODI (thermal neutrons), the strain scanner STRESS-Spec (thermal neutrons), the single crystal diffractometers HEIDI (hot neutrons), POLI (hot neutrons, three-dimensional polarization analysis) and RESI (thermal neutrons), the protein diffractometer BioDiff (cold neutrons) and a Laue camera (thermal neutrons). A high intensity time-of-flight powder diffractometer POWTEX (thermal) and an extreme pressure diffractometer SPHIRE are under construction in the Guide Hall East.

Small angle diffraction and reflectometry: Small angle scattering characterizes the ensemble average of mesoscopic structures from typical 1 nm to 10 μm , i.e. it fills the gap between atomic resolution and structures visible with light. At MLZ the classical pinhole instruments KWS 1, KWS 2 and SANS-1 are as long as 40 m, have large two dimensional detectors and cover routinely reciprocal space from $1\text{--}10^{-3} \text{ \AA}^{-1}$. KWS 3 works on the focusing mirror principle and extends the range in reciprocal space to $< 10^{-4} \text{ \AA}^{-1}$. The reflectometers NREX, REFSANS and MARIA cover similar dimensions like the small angle cameras, but now in reflecting geometry exploring the vertical dimension of surfaces and interfaces. Furthermore, all three instruments allow the so-called grazing incident mode thereby exploring the lateral dimension of surfaces.

Fig. 8 Floorplan of the FRM II with the neutron guide system. FRM II/TUM

Fig. 9 View into the experimental hall of the FRM II. Bernhard Ludewig

Inelastic neutron scattering: Inelastic neutron scattering is the method of choice to tell how the atoms or their magnetic moments move. At MLZ five 3-axis spectrometers PUMA, PANDA, TRISP, MIRA and KOMPASS complement each other in time-spatial resolution and spin analysis. Among these, TRISP is the world champion for analyzing phonon lifetimes. To

reveal stochastic movements in hard as well as soft matter even higher resolution in energy or time is asked for. This is achieved by NSE (spin echo), RESEDA (resonance spin echo), SPHERES (backscattering) and TOFTOF (time-of-flight). NSE and TOFTOF stand out having the lowest background for their kind of instrument. Finally, DNS focuses on the detection of magnetic fluctuations. Under construction is TOPAS, a thermal time of flight spectrometer featuring polarization analysis and high flux.

Imaging and element analysis: whereas all above mentioned instruments measure in reciprocal space neutron imaging displaces objects in direct space. ANTARES (cold neutrons) and NECTAR (thermal and fission neutrons) are doing so by transmission measurements. Collecting typically some hundred transmission pictures under different angles enables tomography, i.e. producing a three-dimensional picture of the attenuation coefficients of the object. Highest spatial resolution achieved so far at ANTARES is 12 μm . One cold neutron beam is dedicated to Prompt Gamma Activation Analysis (PGAA). By means of focusing optics the world most intense beam of cold neutrons ($4\text{--}6 \times 10^{10} \text{ n cm}^{-2} \text{ s}^{-1}$) hits the sample with a spot size $< 1 \text{ mm}^2$. In principle, all the chemical elements can be analyzed with PGAA. The major advantage of the method is its capability in the analysis of light elements. Elemental analysis as low as 0.1 ppbw can be achieved.

Nuclear, particle and astrophysics: Going back to Heinz Maier-Leibnitz nuclear, particle and astrophysics with neutrons have a large tradition at TUM. Some of the questions in this field can be dealt with the instruments PGAA and the positron source NEPOMUC. However, the most versatile tool would be an intense beam of cold neutrons and an ultra cold neutron source. Both are currently under construction. MEPHISTO, as the cold neutron beam is called, will deliver a gold capture flux of $2 \times 10^{10} \text{ n cm}^{-1} \text{ s}^{-1}$ on a beam area of $60 \times 106 \text{ mm}^2$. The UCN source will be installed in the through-going beam tube SR 6, it will operate with a solid D_2 target and expects UCN flux densities in the order $10^5 \text{ cm}^{-2} \text{ s}^{-1}$ in an energy band of 100–230 neV. Both sources will serve for high precision experiments like the β -decay of the neutron, its life time or eventual electric dipole moment. The ultimate goal of these experiments is to find evidence for physics beyond the standard model.

Science with positrons: NEPOMUC provides a high-intensity low-energy positron beam for applications in solid state and surface physics as well as for fundamental research in nuclear and atomic physics. The intensity amounts to $> 10^9$ moderated positrons per second at a beam energy of $E = 1 \text{ keV}$. The remoderation device of NEPOMUC enhances the brightness of the positron beam and hence enables positron experiments which are highly resolved in space or/and in the time domain. The remoderator is based on the stochastic positron cooling in a W(110) single crystal and reemission of thermalized positrons into the vacuum with discrete energy. For most of the measurements the brightness enhanced positron beam is used. By a central, fivefold beam switch the positron beam is delivered to one of the five experiment beam lines:

Pulsed low-energy positron system (PLEPS), Coincident Doppler-broadening spectrometer (CDBS), Positron annihilation induced Auger-electron spectrometer (PAES), Scanning Positron Microscope Interface (SPM Interface). The fifth beam line is for the multi-purpose open beam port (OP) [<https://www.mlz-garching.de/nepomuc>].

Instrumentation at MLZ is under continuous development. The actual status and detailed information can be found on the MLZ homepage under “Experimental facilities – Heinz Maier-Leibnitz Zentrum”.

An outlook

Despite the decision of the German government to phase out of nuclear energy by the end of 2022 there is no doubt that research reactors are not affected by this development. On the other hand, as of 2020 only two research reactors are still in operation in Germany, namely the small 100 kW TRIGA reactor of the Johannes Gutenberg University in Mainz and FRM II. Consequently, science as well as technical, industrial and medical applications based on the use of neutrons will be focused even more on FRM II than today. Numerous precautions have been taken in order to guarantee the availability and attractiveness of FRM II for a long-term future.

With respect to operation the supply of fuel elements and the external storage of spent fuel have been secured by means of long-lasting contracts. The scientific use will be extended by means of one or maybe even two additional neutron guide halls housing additional experiments. The fleet of secondary sources is about to be extended in the near future by an ultra-cold neutron source providing neutrons with temperatures in the mK range.

In parallel, also the use of neutrons for industrial and medical applications will be of growing importance. Neutron scattering will continue to provide important contributions to material science dealing with questions as different as the better understanding of the charging/discharging of Li-ion batteries or the knowledge about the ultimate lifetime of industrial components. The irradiation facility dedicated to the production of ^{99}Mo is under construction and will contribute considerably to satisfy the growing European need for $^{99\text{m}}\text{Tc}$, the indispensable “working horse” in nuclear-medical diagnostics. The demand for further radioisotopes like e.g. ^{166}Ho is increasing and needs to be met. The same applies to neutron transmutation doped Si that is needed e.g. for high-power switches for the DC long distance current transmission from the off shore wind based energy production to the users in the industrial centers of the country.

Taking into account all what has been said above it is obvious that a multi-purpose research reactor providing neutrons for a broad band of applications will be needed urgently also in the future and FRM II and MLZ will contribute their share for the benefit of science as well as for the entire society.

Introduction

The MARIA research reactor is named after Maria Skłodowska-Curie, a great Polish physicist, twice Nobel prize winner (1903 in physics, jointly with H. Becquerel, and 1911 in chemistry). It is currently the only nuclear reactor in Poland; however, it is the outcome of a long history of atomic research and development. The nuclear site NCBJ (National Centre for Nuclear Research, former IBJ i.e. Institute for Nuclear Research A. Sołtana) is located in Otwock-Świerk, 30 km from Warsaw, Poland (Fig. 1). The technical specifications for the reactor, at that time with the codename R-2 (second reactor), were initially proposed in 1964, and they were based upon the experience with the VVR-S type (a Soviet design) EWA research reactor that was operational since 1958. EWA was an acronym for (in Polish) Experimental-Water-Atomic but it was effectively a modified (2–10 MW) Soviet VVR-S design. Requirements for the new reactor included: production of radionuclides for the needs of industry and medicine, testing of nuclear reactor materials, coolants and reactor fuels in rigs and loops, neutron modification of materials, activation analysis and autoradiographic techniques, and basic and applied research using neutron beams. Additionally, in-core irradiation positions and neutron beams were designed for medical research and training in reactor physics and technology.

Because of the political situation at the time, the only supplier of nuclear technology could be the USSR, which initially proposed the RFT type (water cooled uranium-graphite reactor) nuclear reactor technology. During the negotiations (and as a result of Polish lobbying), this was changed to the design of the MR-type reactor. The original Soviet project was modified in Poland to meet the specific needs by adding horizontal neutron beams, and vertical channels for the production of the radioisotopes. Also, the individual solutions differ with the MR, including the reactor pool cooling system and in-core structures. Some of the designs were tested in the MARYLA (general purpose zero power reactor), and two specially built for that purpose: ANNA (RFT model) and AGATA (MR model).

The construction of the MARIA reactor began in 1969 and was carried out by the Institute for Nuclear Research (pol. Instytut Badań Jądrowych), the reactor went critical on December 18, 1974. MARIA operated until 1985 and then it underwent a thorough modernization, including replacement of the reactor control system, inspection of graphite reflector blocks, supplementing the core configuration with additional beryllium blocks, construction of a biological radiation shield, modernization of the reactor cooling system equipment, modernization of reactor technological ventilation systems and installation of the fuel channels flow and temperature control system. During the modernization, the Chernobyl disaster happened, so its initial scope was broadened: an emergency fuel channels cooling system and redundant covers over the horizontal neutron beams were added (Pytel, 2015). The reactor resumed regular operation in 1993 and is the only nuclear reactor operating in Poland today (the EWA reactor was shut down in 1995).

MARIA is constantly being modified in order to improve its safety and scope of scientific and technical applications. The most significant changes concern nuclear fuel. Initially, the MARIA reactor used fuel enriched in U-235 to 80%. In 2003, the reactor was converted to 36% enriched fuel and in 2005–06 the decision was made to use a fuel designed with the same enrichment but with a smaller mass of uranium in a single fuel element. In 2009, tests began on a new type of French manufactured MC-5 fuel element with enrichment below 20%. Beginning in 2012, the process of a phased conversion started and the total conversion of MARIA into low-enriched uranium fuel (LEU) was completed in 2014. This change of fuel required a refurbishment of the reactor cooling system in 2013 following a cooling tower replacement in 2012. That same year, the low-enriched uranium Russian MR-6 fuel elements were

Fig. 1 MARIA reactor and technological-administrative buildings. Courtesy of NCBJ (National Center for Nuclear Research).

tested in MARIA which allowed the reactor to have two sources of fuel elements for flexibility. Additionally, MARIA received a license in 2020 for a special purpose MR-2 fuel design that enables sample irradiation inside the central cooling channel of the fuel element in high fast neutron flux. In 2016, repatriation of the used and spent HEU fuel elements to the Russian Federation were completed as part of the International Global Threat Reduction Initiative (GTRI) coordinated by the US Department of Energy and the International Atomic Energy Agency.

In 2014, the INSARR (Integrated Safety Assessment of Research Reactors) of the International Atomic Energy Agency (IAEA) mission recommended an upgrade of the fuel temperature measurement system to decrease the delay time of safety signals; In 2017, follow-up INSARR mission positively assessed the state of nuclear safety of the reactor and implementation of recommendations and suggestions.

Currently, the MARIA reactor has a license to operate until 2025, and thanks to regularly carried out modernizations and upgrades, it is expected to operate at least until 2050.

MARIA reactor design

Fuel design

Two types of low-enriched fuel elements are currently being used in the MARIA reactor (**Fig. 2**):

- MC-5/485, French production (by Cerca-Areva), with 19.75% enrichment, a dispersion of a uranium silicide alloy powder (U_3Si_2) in Al, and
- MR-6/485, Russian production (by Novosibirsk Chemical Concentrates Plant, TVEL), with 19.70% enrichment, a dispersion of UO_2 in Al.

Both fuel element designs are clad with aluminum. Each fuel element has a form of six (MR) or five (MC) concentric tubes.

For the French MC-type fuel, U_3Si_2 powder is produced by melting uranium and silicon together and then grinding into powder of a specific size. Then it is mixed with aluminum powder and compressed between two Al covers, forming a sandwich, and transformed into a thin plate by hot and cold rolling and then cut and curved to obtain the right dimensions. Each fuel element tube is fabricated using several curved fuel plates. Plates in the outermost tube, acting as a support tube, are welded together, while in the others the curved fuel plates are attached with stiffeners. The tubes (except for the outer tube) are embedded in guides with a clearance provided for axial thermal expansion.

The Russian MR-type fuel is produced as a tube in the process of direct extrusion. The fuel element consists of six concentric tubes, the third of which from the outside also plays a supporting role, because the structural elements of the fuel element are attached to it. The other tubes can move along the axis within a certain thermal clearance. Each tube consists of three layers: inner and outer aluminum alloy cover and the fuel core. In both types of fuel, the tubes are spaced equally, due to the use of spacers, in order to ensure appropriate cooling channel dimensions. Parameters of both types of fuel are presented in **Table 1**.

Fig. 2 Fuel elements cross section. At the top there is the French MC-5 design and at the bottom there is the Russian MR-6 design. Courtesy of NCBJ (National Center for Nuclear Research).

Table 1 Parameters of fuel currently used in MARIA reactor.

Parameter	MC-5/485 (19.75%)	MR-6/485 (19.70%)
Total length of the fuel element	1315 mm	1380 mm
Nominal fuel length	1000 mm	1000 mm
Assembly outer diameter	74.6 mm	74.8 mm
Fuel type	Dispersion of U_3Si_2 in Al	Dispersion of UO_2 in Al
U-235 content	485 g	485 g
Uranium density in the fuel layer (tube)	4.79 g cm^{-3}	3.59 g cm^{-3}
Fuel layer thickness	0.8 mm	0.8 mm
Heat exchange surface	1.29 m^2	1.72 m^2
Mass ratio U-235/ H_2O in the fuel element at $T = 20^\circ$	0.233	0.940
Diameter of the outermost fuel tube	70 mm	70 mm

Reactor characteristics

The critical parameters of the two types of fuel used in the MARIA reactor slightly differ. In the MC fuel there is angular unevenness of power density distribution in fuel tubes, related to discontinuities in the fuel distribution at the boundaries of fuel plates as well as with the presence of plate stiffeners. The problem does not occur in the MR fuel because of the different design. Parameters critical for MARIA reactor operation are listed in [Table 2](#).

Fuel conversion

Initially, the reactor operated on Russian fuel MR-6, in the form of a dispersion of UAl in an Al matrix with 80% enrichment. In response to IAEA recommendations, the fuel was gradually replaced with less enriched material. The conversion took place in two steps: from 80% to 36% and from 36% to below 20%. The 80% enriched fuel was gradually replaced by lower enriched elements (36% enrichment, in the form of a dispersion of UO_2 in Al, from the same manufacturer). The fuel design remained unchanged with the amount of U-235 increased, with concurrent enhancement of the fuel matrix density. To maintain fuel performance, more low-enriched uranium was required to be used in the fuel matrix which significantly increased the amount of U-238 in the fuel. As a result, a decrease in available neutron flux occurred (due to the additional parasitic U-238 content) while maintaining the thermal characteristics of the fuel. Maintaining neutron flux at the previous levels was only possible by increasing the thermal power of the fuel and raising the total power of the MARIA reactor. With the first stage of conversion completed, the next step was replacing the fuel containing 540 g of U-235 with new elements of the same enrichment but with a U-235 content of 430 g (same manufacturer). This process took place in years 2005–06. The result of this change was a significant decrease in the release of fission products to coolant and the possibility of higher burn-up with the more robust fuel design. Since 2005, a full core conversion to low enriched fuel was planned and scheduled as part of the US Global Threat Reduction Initiative (GTRI). In 2009, tests of French fuel in the form

Table 2 General parameters of MARIA reactor core.

Parameter	Value
Neutron flux:	
• Thermal, in core	• $2.5 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$
• Thermal, in reflector	• Less than $3 \times 10^{13} \text{ n cm}^{-2} \text{ s}^{-1}$
• Fast, irradiation position	• Up to $1 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$

of U_3Si_2 dispersion in Al with 19.75% enrichment were started. Positive test results led to the decision to approve the fuel for reactor operation. However, hydraulic calculations showed that the introduction of the new fuel would result in an increase in the pressure drop across each fuel channel, as the new fuel was characterized by higher hydraulic resistance and smaller heat exchange surface. To maintain a safe thermo-hydraulic regime an increase of the coolant flow through the fuel channels was needed. An upgrade of the fuel channel cooling system was designed and installed in 2013 which replaced the single-speed main circulation pumps with two-speed pumps. In addition, a newly designed decay heat removal system with separate circulation pumps was installed at the same time. The full HEU to LEU core conversion program was completed in 2014.

Core configuration

MARIA is a 30 MW pool type reactor of a unique design with individual pressurized fuel channels for cooling the reactor fuel. Each channel consists of an outer aluminum tube containing an individual fuel element and cooled by dedicated piping connected to the reactor cooling system. Graphite is used as a reflector surrounding the reactor core and water and beryllium as moderators between and around fuel channels. The core consists of 28 fuel channels situated in a beryllium matrix, enclosed by graphite blocks forming the reflector. It is also equipped with approximately 26 vertical channels used for irradiation and 8 horizontal channels (seven operational and one still only in conceptual design) for other experiments requiring a radiation beam. The whole core is placed in an aluminum housing, called the basket which is supported on a table or platform at the bottom of the reactor pool. The top view of the core is shown in Fig. 3. For physical reasons, the fuel grid pitch in the middle of the height of the fuel in MARIA reactor core is 13 cm. In contrast, structural considerations, to provide more space, require a much larger grid pitch at the level of connection of the cooling water connections as well as at the level of control rod drives above the pool water level. Effectively, the MARIA reactor core was designed as a truncated cone with spacing between fuel channels smaller at the bottom of the core than at the top. This is another unusual feature of MARIA as most research reactors, with the Belgian BR2 being a notable exception, are designed with fuel elements or assemblies in vertical orientation.

The beryllium matrix consists of 45 blocks and moldings of 10 different uncladded shapes. The size of the full block (precisely the aluminum cap) at the top is 14 cm, and at the bottom 12 cm. All the fuel channels have an outer tube diameter of 7.9 cm. They

are placed in the spaces created by the corner cuts in the beryllium blocks and embedded in the mounting plate. The control rods of the reactor, also used as shim rods, have B_4C for neutron absorption and are placed in the central channels of the beryllium blocks. The design of the control rod drives and channels for all types of rods are the same which allows moving them or changing the configuration as necessary. Fuel assemblies and core configuration are usually shuffled before each reactor start-up. The number of necessary fuel elements is usually 28; however, the total number of fuel elements can be changed as needed for a particular reactor cycle. A typical core configuration is shown in Fig. 4. Graphite blocks have an analogous design as beryllium blocks, except that they do not have recessed corners. The graphite blocks are clad with aluminum. Some graphite blocks also have holes in the center (along the entire height of the block) that can accommodate isotope production channels. To allow irradiation of large experiments or materials such as for silicon doping, a large 4 by 4 grid area is established with a special neutron moderation curtain between the reactor and the experiments.

Cooling systems

The MARIA reactor is cooled by two separate primary cooling systems: the fuel channel cooling system and the reactor pool cooling system. During regular operation of the reactor, coolant flow in the fuel channels is provided by two main pumps (with two in standby) providing a total flow of $660 \text{ m}^3 \text{ h}^{-1}$. Additionally, two auxiliary pumps operate in the bypass mode, and their role is to provide forced cooling after the reactor shutdown. A small by-pass flow is sent through the pressurizer to degas the coolant of dissolved gases. The fuel channel cooling system is shown in Fig. 5. In the MARIA reactor, each fuel element is placed in an individual fuel channel connected to inlet and outlet manifolds through pipelines and valves. The channels are pressurized with the inlet pressure of 1.7 MPa, and the individual flow is set at $25\text{--}30 \text{ m}^3 \text{ h}^{-1}$, the overpressure is supplied by the main pumps and a pressurizer. A set of thermometers installed in the cooling system enables measuring coolant inlet temperature and outlet temperature of individual fuel channels. This capability enables the measurement of thermal power, coolant flow, and temperatures in each fuel element. During normal operation, the maximum temperature of the fuel element cladding does not exceed 155°C . Each of the fuel channels is also connected to the failed fuel detection system. The system enables monitoring of the fission products release from individual fuel elements.

The pool cooling circuit ensures safe operating conditions for the beryllium matrix, graphite reflector, control rods, target materials in the irradiation channels, experimental devices, and structural elements of the reactor core. The heat generated in non-fuel core elements comes mainly from gamma radiation emitted from the fuel, as well as from neutron induced reactions in the core materials. A significant part of the heat received by the pool cooling circuit comes from the heat exchange between the fuel channels and the pool. The pool water itself provides radiation shielding and acts as a biological shield. It is a forced circulation, low pressure, open circuit. The secondary cooling circuit is mutual for both systems. It is connected to them by a set of heat exchangers, and the heat is dissipated in the atmosphere via a forced draft cooling tower.

Fig. 5 Fuel channels cooling system diagram including main and auxiliary pumps, pressurizer, heat exchangers, water supply tanks and emergency core cooling system marked. Courtesy of NCBJ (National Center for Nuclear Research).

Safety systems

The reactor protection system (RPS) is based on 13 absorbing rods divided into three categories: safety rods, shim rods and an automatic control rod. Although the safety rods are the main protection system, both safety rods group and shim rods group are capable of scramming the reactor. The RPS receives information from the following safety systems: reactivity control, SSC's readiness information, instrumentation and power supply. Moreover, several signals deriving from the control room buttons including manual emergency fuel channel cooling system activation, are included in RPS.

Reactivity control system

The reactivity control system functions range from control of slight deviation from criticality during normal operation to its safety role during postulated initiating events. The following devices are included in the system:

- Start-up channel based on a fission chamber with the following outputs: reactor period and neutron flux (low and medium measurement ranges);
- Log amplified lines based on ionizing chambers with the following outputs: neutron flux (medium and high measurement ranges);
- Linear amplified lines based on ionizing chambers with the following outputs: reactor period and neutron flux (medium and high measurement ranges).

Other instrumentation systems

There is a group of additional measurement systems which provide the global temperature, pressure and flow measurements as well as water conductivity, vacuum pressures and stack effluences monitoring. However, unlike the pool type reactors, the MARIA reactor design included provisions for nuclear power plant fuel assemblies testing. Therefore, an additional surveillance was needed and fulfilled by the following instrumentation systems:

- Surface contamination and flawed fuel elements monitoring in each fuel channel;

- Inlet and outlet temperature measurements of coolant in each fuel channel;
- Flow measurement in each fuel channel;
- Pressurizer water level.

Experimental facilities

Experimental facilities

The MARIA reactor was designed to operate with several experimental devices in parallel. The most important of them are:

- vertical irradiation channels for radionuclide production;
- reactor test rigs for structural materials, biological samples and reactor fuel studies under stationary conditions ([Krzysztozek, 2013](#));
- large sample channels for electronic, concrete and other materials irradiation;
- horizontal experimental channels for neutron beam studies.

The reactor construction allows installing various kinds of irradiation facilities and neutron sources.

The following channels are available:

- 2.3 cm diameter channels in beryllium blocks;
- 2.8 cm diameter channels in the graphite reflector;
- 3.8 cm diameter channels in the graphite reflector;
- 4.6 cm diameter channels inside the modified fuel element MR-2;
- bulk material irradiation facility for large-size (up to 8.5 cm in diameter and 90 cm height) target materials
- channels equipped with a hydraulic transport ("rabbit") system located in the beryllium and graphite area of the reactor core.

The customized fuel channel can be used to irradiate fission materials, like targets or fuels, under strictly controlled conditions. Such technology has been applied for irradiation of uranium targets for ^{99}Mo production. This activity plays a special role in the utilization of the MARIA reactor.

Following the shortage of the key medical radioisotope ^{99}Mo and its daughter $^{99\text{m}}\text{Tc}$ related to a long-term reliability, the MARIA reactor declared its readiness to irradiate the uranium targets. The program has been successfully launched and the irradiation of uranium targets has been performed since 2010 (HEU targets). Since 2017 LEU targets have been irradiated.

The technology implemented in the MARIA reactor for ^{99}Mo production employs a specific construction of fuel channels with a cooling system, mechanical hardware and measuring system. The system is linked to the measuring system of thermal-hydraulic parameters of the each of the reactor fuel element.

Thanks to the versatility of the MARIA reactor construction, there are plenty of possibilities of neutron beam and core neutron field utilization. A set of irradiation channels located in the beryllium moderator matrix can provide neutron flux density of up to $2.5 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$. Their performance and neutron spectrum may vary depending on the distance from the fuel elements and the position in the core; however, the spectrum is still typical for the thermal reactor core. Four of the in-core irradiation positions comprise the hydraulic rabbit system, allowing irradiation time control with one-second resolution. One of the rabbit system channels is located aside of the core, therefore providing a well-thermalized neutron flux of up to $2.5 \times 10^{13} \text{ n cm}^{-2} \text{ s}^{-1}$.

The MARIA reactor is equipped with bulk material irradiation facility located at the peripheral part of the core, behind the thermal neutrons shielding screen. The fast neutron flux reaches $3 \times 10^{12} \text{ cm}^{-2} \text{ s}^{-1}$ in the most powerful position, while the thermal neutron flux density is reduced below $3 \times 10^{10} \text{ cm}^{-2} \text{ s}^{-1}$. The facility consisting of eight channels enables to irradiate large-size (up to 85 mm in diameter and 900 mm height) target materials, devices or its components.

A special 14 MeV neutron irradiation channel is operated in the MARIA reactor core. The device consists of thermal-to-14-MeV neutron converter based on lithium-6 and deuterium compounds ([Prokopowicz, 2015](#)). The principle of its operation is based on two-step reactions induced by thermal neutrons. The 14 MeV neutron flux density exceeds $1 \times 10^9 \text{ n cm}^{-2} \text{ s}^{-1}$ inside the converter with cut-off thermal neutrons at the same time. The neutron energy spectrum depends on the converter location in the reactor core and is similar to the one in thermonuclear devices. Its loading capacity is ca. 60 cm^3 (four containers, $\varnothing 15 \times 90 \text{ mm}$ each). The converter is dedicated to material research, i.e. irradiation tests of new structural materials for Generation IV nuclear reactors and fusion facilities. It can also be used to obtain radiopharmaceuticals produced by fast neutrons in threshold reactions.

The MARIA reactor design offers an excellent irradiation capabilities in thermal neutron spectrum with a flux up to $2.5 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$, but fast neutrons flux is limited below $5 \times 10^{13} \text{ n cm}^{-2} \text{ s}^{-1}$. To increase the irradiation capabilities in the fast flux a modified fuel assembly (MR-2) design was proposed with a place for target irradiation in the middle of the element – this feature would increase the fast flux up to $1 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$.

The MR-2 fuel can hold an irradiation container with a diameter of $\delta = 34 \text{ mm}$ $\delta = 34 \text{ mm}$ along the whole active length of the fuel that is 1000 mm, the total volume of irradiation equals 90 dm^3 .

The reactor is also equipped with a facility for neutron transmutation doping of silicon single crystals. The vertical neutron flux distribution to be available in graphite reflector together with additional shaping by means of titanium absorber screens has been adopted for achieving high degree of axial and radial doping distribution uniformity. The above solution allowed to achieve the

simplest technical construction and very high quality level of doped silicon crystals. The reactor design allows installing various in-pile experimental facilities like rigs and loops. Recently, thermostatic irradiation rigs are being prepared to be installed in the MARIA reactor core. The rigs can be inserted to the vertical openings inside or between beryllium blocks. The mounting slab over the core allows fixing the upper part of the rig.

Neutron beams characteristics

The neutron beam in the MARIA reactor is streamed through horizontal channels which pass through the biological shield and the reactor pool to the graphite reflector surrounding the core. Some of them are directed towards the core, while others are arranged tangentially, they provide more thermalized yet weaker beam. In the past, the horizontal channels used to be utilized for fundamental research, supplying the research equipment with the beam of intensity up to $3\text{--}5 \times 10^9 \text{ n cm}^{-2} \text{ s}^{-1}$. The research equipment consisted of a wide array of facilities for different applications: a radiography facility, an autoradiography facility for examining paintings, an abiaxial diffractometer for studying crystalline and magnetic structures, a diffractometer for low angle scattering experiments, a low-angle neutron scattering spectrometer, a polarized neutron spectrometer, a triaxial spectrometer for testing network dynamics and a triaxial spectrometer for inelastic scattering.

Currently the equipment undergoes modernization. One of the channels will provide a newly designed biomedical research facility with a neutron beam. It will be primarily dedicated for boron-neutron capture therapy research and other medical purposes such as development of therapeutic and diagnostic carriers or for beam treatment planning and surrounding dosimetry. A neutron converter, which will be installed at the channel inlet, will amplify epithermal and fast neutron flux. The remaining channels are going to be equipped with state-of-art experimental instruments for neutron scattering biological studies (Gryziński, 2015).

Overview

The High-flux Advanced Neutron Application Reactor or HANARO is a 30 MW research reactor. It is located at the site of the headquarters of Korea Atomic Energy Research Institute (KAERI) in Daejeon, Republic of Korea. Based largely on its previous experience of operating two TRIGA reactors for more than two decades, KAERI established the design requirements, developed the detailed design, and constructed HANARO. At the conceptual design stage, KAERI collaborated with the AECL of Canada, and later on it realized the design concepts explored during the collaboration.

The HANARO complex consists of a reactor building, Cold Neutron Research Facility (CNRF), Radioisotope Production Facility (RIPF), Irradiated Materials Examination Facility (IMEF), and several auxiliary buildings such as cooling towers and a cryogenic equipment building for the cold neutron source. Fig. 1 shows the HANARO complex.

In addition to the complex, KAERI has a fuel fabrication factory for research reactors, which manufactures uranium silicide fuels for HANARO, plate-type uranium-molybdenum fuels, and low enriched uranium targets for ^{99}Mo production by fission for medical applications. HANARO is also supported by KAERI's other infrastructures. For example, a thermal hydraulic test loop outside of the HANARO complex is used for testing the mechanical integrity of newly developed irradiation capsules that will be loaded in HANARO.

Since the initial criticality in February 1995, HANARO has been gradually evolving. After resolving an early stage regulatory issue on the fuel integrity that allowed power operation only up to 80% of the rated power, HANARO began the operation at full power of 30 MW in 2004. Four KAERI-made fuel assemblies were first loaded in 2005, and since then HANARO has used KAERI-made fuels in full. Meanwhile, the neutron science in Korea met a turning point with the inauguration of the CNRF in 2010. Instruments

moved to the CNRF from the reactor hall began to utilize cold neutrons, and new instruments have been installed one by one. The areas of neutron irradiation for industrial and medical sectors have been growing as well. For instance, since HANARO began the service of neutron transmutation doping of silicon ingots in 2003, its share in the world market has grown significantly. Production of radiopharmaceuticals for domestic use is another example. In 2014, HANARO celebrated 3000 days of operation. Furthermore, as an International Center based on Research Reactor (ICERR) designated by the IAEA in 2019, KAERI provides researchers from around the world with access to HANARO and associated facilities more effectively than before.

Design features

HANARO is a 30 MW, multipurpose, pool type research reactor that uses rod-type, low enriched uranium silicide fuels (Kim et al., 1996). Table 1 shows its design features.

HANARO uses two types of fuel assemblies and the full core consists of 20 hexagonal and 12 circular assemblies. Each assembly is loaded into a flow tube and locked in the bottom grid plate. Four control rods called CAR are for the power control while four shutoff rods are fully withdrawn during power operation. Each control or shutoff rod is a hafnium tube and it travels vertically, encompassing a circular fuel assembly. The core is cooled by the upward, forced convection of light water and flap valves provide a loop for natural convection through the reactor pool when necessary. The reactor concrete island consists of three pools: a reactor pool, a service pool, and a spent fuel storage pool. The reactor building is a confinement maintaining a negative pressure of about 50 Pa.

Fig. 2 shows the core and the heavy water reflector along with the arrangement of horizontal beam ports and vertical irradiation holes. The core is inside of the curvy rectangle in the center, called the inner shell of the heavy water vessel, and a large circular heavy water vessel surrounds the core. Hexagonal fuel assemblies are shown in blue and circular assemblies in yellow. Four circular assemblies are loaded outside of the core.

Three vertical irradiation holes in the core are for the tests of structural materials or nuclear fuels that usually require high neutron fluence. At the central hole (CT), the thermal neutron flux measures up to $4.5 \times 10^{14} \text{ cm}^{-2} \text{ s}^{-1}$, and the fast neutron flux above 1 MeV is about half of the thermal flux. As shown in Fig. 2, the reactor core is rectangular in order to increase neutron leakage from the core into the reflector. Along with the superior moderating ratio of heavy water, this design results in high thermal neutron flux in the reflector region, 0.3 to $2.0 \times 10^{14} \text{ cm}^{-2} \text{ s}^{-1}$ in irradiation holes and 0.4 to $2.5 \times 10^{14} \text{ cm}^{-2} \text{ s}^{-1}$ at beam port noses. The fast neutron flux level in the reflector is lower than the thermal flux by an order of two or more.

In the reflector region, there are a total of 33 vertical holes available for neutron utilization. These include one hole for producing cold neutrons (CNS in Fig. 2), three holes connected to pneumatic transfer systems for the neutron activation analysis (PTS), two for

Table 1 Design features of HANARO.

Category	Description
Type of reactor	Open tank in pool
Thermal power (MW)	30
Thermal neutron flux ($\text{cm}^{-1} \text{ s}^{-1}$)	Up to 4.5×10^{14} at core center Up to 2.5×10^{14} in reflector region
Fuel	
Shape of fuel element	Finned rod
Shape of fuel assembly	Hexagonal (36-rod assembly), Circular (18-rod assembly)
Fuel meat	U_3Si in aluminum matrix, 19.75% enriched uranium
Effective fuel length (mm)	700
Control element	
Absorber material and shape	Hafnium, cylindrical
Number of elements	4 for control, 4 for shutoff
Drive mechanism	Stepping motor, top-mounted
Fluidic system	
Coolant	Light water
Core cooling method	Forced convection, upward flow
Reflector	Heavy water
Structural material of reactor	Mostly aluminum, Zircaloy-4 (flow tubes and heavy water vessel)
Instrumentation and control	Digital except reactor protection system
Type of reactor building	Confinement
Neutron beam port	
Angle to the core	Tangential
Number of ports	7
Number of irradiation holes	3 in core, 33 in reflector region

Fig. 2 Plan view of core and reflector region.

the neutron transmutation doping of silicon ingots (NTDn), two large diameter holes mainly for the material testing (LH and HTS), and other small holes of 6 cm in diameter for radioisotope production and other irradiation purposes (IPs).

The neutron beam ports in HANARO include one cold neutron port (CN in Fig. 2), one for neutron radiography (NR), one for ex-core neutron irradiation (IR), and four standard ports (STn). HANARO produces cold neutrons by cooling down thermal neutrons in a double-wall container of liquid hydrogen, called a moderator cell, in the reflector region. A helium refrigeration system maintains liquid hydrogen at 22 K, and it results in the cold neutron characteristic temperature of about 26 K, which corresponds to a wavelength of 0.6 nm (Lee et al., 2012). The CN port views the cold neutron source, and cold neutrons travel to the CNRE, a building next to the reactor building, through cold neutron guides extended from the CN port. There are five, multi-layer nickel-titanium coated supermirror guides that eventually branch into seven (Cho et al., 2011). Each guide has a different curvature for removing gamma rays and fast neutrons at arrival at the neutron instruments. The cold neutron fluxes at the monochromator and neutron velocity selector position are in the range of 0.4 to $1.4 \times 10^9 \text{ cm}^{-2} \text{ s}^{-1}$, depending on the neutron guide and instrument.

Reactor operation

A usual cycle of operation consists of 28 days of continuous operation and 14 days of shutdown for maintenance and fuel reloading. Among the 32 fuel assemblies in the core, typically five assemblies are replaced every cycle. The operators work in three shifts and each shift is staffed with three operators including one senior reactor operator. The control room must be attended always, even during a shutdown period.

The HANARO complex is regulated by the Nuclear Safety and Security Commission, which is the governmental nuclear regulatory body. The regulatory activities include biennial inspection of the facilities, biennial quality assurance audit, periodic safety review every 10 years, and investigation of incident if any. In the field, two technical support organizations of the Commission, the Korea Institute of Nuclear Safety and the Korea Institute of Nuclear Nonproliferation and Control, carry out the regulatory activities for the Commission.

In addition to the formal organization in KAERI, there are several committees in different levels. The HANARO steering committee reviews, recommends, and decides the policy for facilitating the utilization, installation or modification of user facilities, and so on. The members are representatives of each user group outside KAERI, a government officer, several KAERI managers, and others such as an expert in regulation. The HANARO safety review committee, chaired by the head of HANARO, reviews the safety concerns of activities such as conducting a new kind of experiment, making revisions to operating procedures, and restarting of the reactor after an unplanned shutdown. The HANARO users association is a group of delegates from individual utilization areas—neutron science, fuel and material test, neutron activation analysis, radioisotope research, and so on.

Utilization

Neutron beam utilization

HANARO has 17 beam instruments in total including nine instruments that utilize cold neutrons (Park, 2013). In addition, it operates the Neutron Radiography Facility (NRF) and the Ex-core Neutron Irradiation Facility (ENF). Figs. 3 and 4 show the instruments and facilities in the reactor hall and the CNRF, respectively.

Fig. 3 Instruments and facilities in reactor hall. NRF: neutron radiography facility; Bio-C: bio-diffractometer with neutron image plate camera; FCD: four circle diffractometer; HRPD: high resolution powder diffractometer; RSI: residual stress instrument; Thermal-TAS: thermal neutron triple axis spectrometer; Bio-D: bio-diffractometer; HIPD: high intensity powder diffractometer; ENF: ex-core neutron irradiation facility; TN-PGAA: thermal neutron prompt gamma activation analysis (above RSI).

Fig. 4 Instruments in cold neutron research facility. G-TS: guide test station; CONAS: cold neutron activation station; DC-ToF: disk chopper time-of-flight spectrometer; Bio-REF: bio-reflectometer; Cold TAS: cold neutron triple axis spectrometer; REF-V: vertical type neutron reflectometer; 40 m SANS: 40 m small angle neutron scattering instrument; 18 m SANS: 18 m small angle neutron scattering instrument; KIST-USANS: KIST ultra small angle neutron scattering instrument.

Neutron diffraction is the only way to distinguish a microscopic structural deformation of light elements such as lithium and oxygen ions in a unit cell. The High Resolution Powder Diffractometer (HRPD) is a tool used to investigate the magnetic structures, multiferroic materials in which ferroelectric and magnetic properties coexist, and an electrochemical reaction mechanism.

The Four Circle Neutron Diffractometer (FCD) is used for a single crystal diffraction. The Bio Diffractometer with neutron image plate camera (Bio-C) and Bio Diffractometer (Bio-D) are dedicated to the investigation of the crystal structure of biological macromolecules such as proteins and nuclei acids. The Residual Stress Instrument (RSI) is used to examine the behavior of material in-situ under load. The RSI is an engineering neutron diffractometer dedicated to the measurement of stress in polycrystalline metals and alloys, and it is useful for investigating defects in, for instance, welding of thick steels. HANARO plans to move most of the above thermal neutron instruments to the CNRF after installation of thermal neutron guides in the future.

Meanwhile, HANARO operates two facilities that utilize thermal neutron beams in the reactor hall. The NRF uses neutrons to provide a transmission image. An example using the NRF is an investigation of water behavior in a fuel cell where hydrogen should be burned efficiently. The ENF is a facility used for various purposes such as a dynamic neutron radiography and developments of neutron detectors such as a SiC detector.

In the CNRF, the neutron instruments utilize cold neutrons produced in HANARO with wavelengths of 0.4–2 nm. A small angle neutron scattering (SANS) technique provides a unique opportunity to study the structure and dynamics of materials at nanometer scale. It is applied to problems involving soft matters such as polymer conformation, morphology, and biological structure. SANS is also powerful in studies on flux-line lattices in superconductors and precipitations in alloys. Three SANSs are in the CNRF (Kim et al., 2013): 40 m SANS (Han et al., 2013), 18 m SANS, and Ultra SANS (USANS). The former two instruments are a conventional pinhole type, while the USANS uses a pair of modified Bonse-Hart-Agalian channel cut crystals as a monochromator and an analyzer. The Korea Institute of Science and Technology has developed and is managing the USANS. Research on the homogeneity and mass density of amorphous metallic glasses is one example of achievements using USANS (Kim et al., 2018). On the other hand, the vertical type neutron reflectometer (REF-V) and Bio-Reflectometer (Bio-REF) are used to study the property of interfaces. The disc chopper time-of-flight neutron spectrometer (DC-ToF) and the triple axis spectrometer (TAS) are the neutron inelastic spectrometers in HANARO (So and Park, 2013). The DC-ToF can provide a wide dynamic range by adjusting incident neutron energy and instrument resolution, while the TAS measures low energy magnetic dynamics. Two kinds of TAS are available in HANARO: a thermal neutron TAS (Thermal-TAS) in the reactor hall and a cold neutron TAS (Cold-TAS) in the CNRF. Lastly, the cold neutron activation station, called CONAS (Sun and Park, 2013), accommodates the instruments for the prompt gamma activation analysis (CN-PGAA) (Hoang et al., 2013), neutron induced pair spectrometer (CN-NIPS), and neutron-induced prompt charged particle depth profiling (CN-NDP) (Park et al., 2014b). The cold neutron PGAA has an advantage of significantly reduced gamma ray background while the capture reaction rate in a sample is comparable to the rate of thermal neutron PGAA.

Neutron irradiation using vertical holes

Fuel and material test

HANARO uses either instrumented or non-instrumented capsules for testing nuclear fuels, new materials under development such as semi- and super-conductor, and materials for current as well as coming nuclear power industry (Choo et al., 2014; Kim et al., 2017). In case of an instrumented capsule, the temperature is controlled up to 700 °C. The thermal and fast neutron fluences are also monitored typically using Nb-Ag and Fe-Ni-Ti wires, respectively. After an irradiation in HANARO, structural parts of the capsule including fluence monitors are dismantled in a hot cell, and specimens are transported to the Irradiated Materials Examination Facility where the fuel burn-up, mechanical properties, and so on are measured and analyzed. Further development of the capsule technology is underway, targeting a fast neutron induced material damage of up to five displacements-per-atom. The Fuel Test Loop (FTL) is the other way to test nuclear fuels (Ahn et al., 2008).

Neutron activation analysis

HANARO provides three stations for neutron activation analysis (NAA). One station is for the instrumental NAA that uses pneumatic transfer systems with which an encapsulated sample in a polyethylene rabbit is irradiated in the reflector region (Chung et al., 2008). There are three irradiation holes with different neutron flux levels and spectra. The Cd ratio, which is a measure to show how well the neutrons are thermalized, is in the range of 10–85 for gold. The other two stations are for the prompt gamma activation analysis (PGAA) using the standard beam port #1 in the reactor hall and cold neutrons in the CNRF, instead of using vertical holes. The thermal neutron PGAA uses the Bragg diffraction technique using pyrolytic graphite crystals (Byun and Choi, 2000). The thermal neutron flux at the sample position is of the order of $10^8 \text{ cm}^{-2} \text{ s}^{-1}$.

Neutron transmutation doping

Neutron transmutation doping (NTD) is regarded as the most effective way to obtain uniform resistivity in a single crystal silicon ingot. HANARO has two vertical holes for NTD. The NTD facility irradiates silicon ingots from 12.7 cm (5 in.) to 20.3 cm (8 in.) in diameter and up to 60 cm in length. A neutron screen inside of an ingot container is designed to yield a flat axial resistivity distribution in an irradiated ingot, and the container rotates at a rate of 20 rpm or less in order to obtain the radial resistivity as uniform as possible. The irradiation time is determined by the initial and target resistivities and some constants. The constants were empirically obtained in HANARO for not only initially n-type but also initially p-type silicon (Kim et al., 2009). A self-powered neutron detector, which is mounted at the top of hole sleeve, monitors the neutron fluence during irradiation. In addition to commercial

services, HANARO conducts R&Ds that focus on how to enhance the uniformity of resistivity and how to reduce crystal defects due to fast neutrons and gamma heating.

Radioisotope (RI) production and R&D

The RIs being produced in HANARO include ^{131}I , ^{99}Mo by (n,γ) reaction, ^{192}Ir , ^{166}Ho , and so on for the medical and industrial sectors (Park et al., 2010). A target material is encapsulated in an aluminum RI capsule for the irradiation in HANARO. An irradiated capsule is put in a cask and transported to the RI production facility (RIPF). The RIPF has four banks and each bank consists of various number of concrete or lead hot cells. Each bank, except Bank II that is a multi-purpose bank, has a production line dedicated to specific RI products: Bank I for ^{192}Ir source for non-destructive test equipment, Bank III for iodine pharmaceuticals such as ^{131}I metaiodobenzylguanidine (mIBG), and Bank IV for $^{99\text{m}}\text{Tc}$ and ^{188}Re generators.

The RI-related R&Ds in HANARO extend to radioisotope thermoelectric generators, micro battery, radiolabeled compounds for medical use, and radiotracers and systems for the diagnosis of, for instance, a petro-chemical plant during operation. In addition, HANARO has developed a technology of ^{99}Mo production by fission using a low enriched uranium target. The technology will be implemented in the Kijang research reactor (Park et al., 2014a), which is under construction in Korea.

International collaboration

As a multipurpose and high neutron flux research reactor, HANARO provides not only domestic but also international users with facilities and instruments in a wide range of R&D areas and neutron irradiation services. The HANARO complex, incorporating the Nuclear Training and Education Center of KAERI, is one of the International Centers based on Research Reactor (ICERRs) designated by the IAEA. Through bilateral arrangements facilitated by the IAEA, the HANARO resources are available to organizations and institutions of IAEA member states. The Korean Neutron Beam Users Association (KNBUA) is a member of the Asia-Oceania Neutron Scattering Association (AONSA), which is an affiliation of neutron scattering societies and represents users in the Asia-Oceania region. HANARO serves the local KNBUA as well as international researchers in the region by providing the facilities, sharing R&D results, and disseminating knowledge through, for instance, the neutron school. HANARO is also involved in the Forum for Nuclear Cooperation in Asia (FNCA). HANARO recognizes that these international collaborations are mutually beneficial. In addition, KAERI provides foreign countries with its research reactor technology on either commercial or non-commercial bases. Examples include construction of a research reactor complex, installation of a specific unit facility such as a cold neutron source, and supply of equipment such as a tracing equipment using radioisotopes. In addition to HANARO as an ICERR, Korea more broadly provides international users with the infrastructures for the education and training through the AGN-201K reactor at Kyung-Hee University which is the Internet Reactor Laboratory designated by the IAEA.

Introduction

In Sanskrit, Dhruva means ‘immovable or unshakable’ and refers to ‘pole star,’ a reference to robust, reliable and safe reactor system. This multi-purpose reactor was built to provide the needed support to an ambitious ever evolving Indian nuclear program. The proposal for building this reactor, referred as R-5 during the project stage that stands for 5th reactor at BARC (Bhabha Atomic Research Centre), was initiated and discussed in 1971 and the first criticality was achieved on August 8, 1985 at 0220 h. **Fig. 1** shows an external panoramic view of Dhruva reactor located at BARC campus. The high power and high thermal neutron flux of $2.0 \times 10^{14} \text{ ncm}^{-2} \text{ s}^{-1}$ and host of experimental beam hole positions and irradiation facilities makes this reactor as one of the top operating research reactors now in the world (IAEA, 2019). Dhruva is a vertical tank type reactor, located in a pool of water called a vault and surrounded by heavy density pile block concrete that works as the biological shield. The reactor uses natural uranium as fuel with aluminum as cladding, heavy water as coolant, moderator and reflector. The primary shutdown devices

Fig. 1 Dhruva reactor—An external view.

comprising of nine shut-off rods having cadmium as absorber of thermal neutrons; and six control/dump valves that dumps moderator from reactor vessel to a dump tank; each provides independent, redundant and diverse modes that assure long term sub-criticality. To isolate the reactor from the outside environment, the reactor and associated process and safety systems are housed in a concrete containment system. For the postulated very unlikely accident scenario that might pose threat of radiation release from the reactor systems, the containment along with reactor building isolation features acts as physical barrier to mitigate and eliminate radiation consequences in public domain. The demineralized water acts as secondary coolant while sea water is used as tertiary coolant or ultimate heat sink during normal operation of the reactor.

The reactor has logged in ~35 years of smooth and safe operation and continues to provide needed research and development support to the nuclear power program and isotope requirements in healthcare, agriculture and industries. Material irradiation studies in support of science and engineering developments has also been one of the areas where Dhruva has been utilized extensively.

Indian research reactor program – A brief overview

For initiating a nuclear programing any country, building of research reactor is the most effective option to make the robust foundation for development and harnessing the application of nuclear energy (IAEA, 2016a). Research reactors in India provided the right ecosystems for, not only Indian nuclear power program, but also R&D support toward meeting the nation's aspirations in application of radioisotope in health care, agriculture and industry.

In 1955 construction of the first Indian research reactor, Apsara—a swimming pool type, 1.0 MW research reactor started and in 1956, the reactor achieved its First Criticality. Apsara operated till 2009, when it was decommissioned after more than 50 years of dedicated service to the nation in the area of nuclear science and technology (Agarwal et al., 2006a). Even when Apsara was in operation, a need was felt for a reactor having higher power and neutron flux more than 10^{13} ncm⁻² s⁻¹. In July 1960 Cirus—a 40 MWth reactor was commissioned (BARC, 2010a). When Apsara on one hand offered a facility for nuclear R&D and training of staff, the Cirus became, as it is perceived, the workhorse of Indian nuclear program. In fact, the initial staff for Indian nuclear power and research reactor design and operations program got their training in reactor design, operation and radiation protection aspects in Cirus reactor. Along with building of Cirus, the fuel fabrication facility, low level waste, water treatment facility and also fuel reprocessing facilities were also developed, at BARC. Between 1970s and 1980s small research reactors, like Zerlina, Purnima series (I, II and III) were developed and operated for lattice physics experiment to firm up the design of Dhruva, PHWRs, Fast breeder reactors and ²³³U fuelled KAMINI reactor.

The Dhruva reactor was commissioned in 1985 and the country had a high flux facility that enabled the needed enhanced capacity of reactor systems for neutron activation analysis, isotope production and engineering experiments which required higher flux (BARC, 2010b). BARC has also been involved in developing the Advanced Heavy Water Reactor (AHWR). To support the experimental requirements for AHWR, a Critical Facility was built and operated mainly to carry out AHWR lattice experiments and core optimization studies. Recently, on September 10, 2018, a 2.0 MWth swimming pool type reactor to augment experimental, isotope and detector testing requirement of the nation has been commissioned (BARC, 2018).

Most of the research reactor program for thermal research reactors, as above, was developed at BARC. India has a three stage nuclear program where the first stage envisages, development of thermal reactors that utilize natural uranium fuel for power production; the second stage comprises a Fast Reactors program that utilizes reprocessed fuel from thermal reactors like Plutonium in the form of Pu-U-C or Oxide along with utilization of Thorium as blankets and breeds fissionable inventory (U-233); the third stage reactor are again thermal reactors using the fissionable inventory available from fast reactor after reprocessing is utilized as fuel like U-233 as fuel in third stage systems (Sinha and Kakodkar, 2003); Here, the Indira Gandhi Centre for Atomic Research (IGCAR), located at Kalpakkam, India has also developed fast research reactors systems. There are two research reactors located at IGCAR, Kalpakkam, viz. a 40 MWe Fast Breeder Test Reactor (FBTR) and 30 kW Kalpakkam Mini (Kamini) thermal reactor. The Kamini reactor is the first research reactor facility in the world operating on U-233 as fuel (IGCAR, 2019). The Expertise available on FBTR has been valuable for construction and commissioning of 500 MWe Prototype Fast Breeder Reactor (PFBR), Kalpakkam (Bhawini, 2019), India.

Major design features of Dhruva

There are over 27 systems in Dhruva that includes (a) process systems required for reactor normal operation like main coolant system, secondary and tertiary coolant system, reactor regulation system, Off-site or Class IV power supply systems, etc.; (b) reactor safety systems which remains standby and gets actuated when there is a demand due to reactor reaching some limiting conditions or a parameter reaches safety system settings, like reactor shutdown systems, decay heat removal system. Systems like Emergency Core Cooling System (ECCS), reactor building Emergency ventilation system are called engineered safety features (ESFs) that come into action only to eliminate/mitigate the consequences of emergency scenarios. There are systems which are also required for actuation and operation of safety systems, called safety support systems, like emergency power supply systems, and compressed air systems have also been provided for the reactor. A simplified representation of process flow schematics of Dhruva is shown in Fig. 2.

Fig. 2 Simplified representation of process flow schematic of Dhruva (Agarwal et al., 2006b).

Reactor physics

As mentioned above, Dhruva is a thermal neutron, heterogeneous, natural uranium fueled reactor, moderated, cooled and reflected by heavy water and has a rated power of 100 MWth. The reactor is natural uranium fueled with seven pin cluster assemblies. The reactor core is contained in a stainless-steel vessel and the core consists of 146 lattice positions including irradiation positions and 9 shut off rods (SOR). The Pneumatic Carrier (PC) facility in pile facilitate short-term irradiation, ≤ 1.0 min, of sample. The core configuration of Dhruva showing apart from fuels, shut-off rods, other experimental assemblies, is given in Fig. 3. Heavy water in the reactor vessel outside the fuel region serves the purpose of top and bottom axial reflectors (~ 30 cm) and also of radial reflector (~ 60 cm). The reactor has a maximum thermal neutron flux of $2.0 \times 10^{14} \text{ ncm}^{-2} \text{ s}^{-1}$ corresponding to a maximum fuel channel power of 1170 kW to meet the demands of research and development in the areas of science and engineering.

The reactivity control and shut down margins are estimated for the most reactive loading with the coolant present in the channels and experimental and irradiation assemblies absent. The reactor power regulation is achieved by varying the moderator level with constant inflow and variable outflow in the reactor vessel. Three independent channels of instrumentation are given for the important safety parameters.

Pile block

The reactor cylindrical pile block is made of heavy density concrete (density 3.5 g/cc). The cylindrical reactor vessel, made of 19.0 mm thick stainless steel—304 (SS-304-L) having an internal diameter of 3720 mm and height of ~ 7000 mm, is located in

Fig. 3 Dhruva pile positions configuration (BARC, 2010b).

Fig. 4 General arrangement of reactor pile block of Dhruva (Agarwal et al., 2006b).

reactor vault as shown in Fig. 4. The pile block concrete and vault water thickness measure 2.4 m and 1.2 m, respectively and provide shielding around the reactor vessel such that radiation field on contact with the concrete surface is well within the limits i.e. < 0.1 mR/h (1 mSv/h). The reactor vessel is supported on the reactor support structure in the vault. The vault has SS-304 lining to reduce the chance of seepage of vault water. The carbon steel end and annular shield ensures that radiation field on reactor top is well within the stipulated limit. The SS inlet plenum and top tube sheet of the reactor vessel has lattice holes to accommodate 146 lattice positions with precision alignment in axial and radial direction to enable smooth entry of ~ 10 m fuel into the Zircaloy guide tubes in each lattice position and other assemblies. Typical core configuration is comprised of 128 fuel assemblies, 9 shutoff rods, and rest for Adjuster Rod, Pneumatic carrier rod, isotope tray rods and corrosion loop experiments and one in-pile loop. The Shutoff rod positions are cooled by compressed air while the tray rods are cooled by heavy water at reduced rate compared to fueled core positions.

The pile and reactor vessel have 16 positions distributed around for beam tube experiments in addition to three positions which are reserved for neutron detectors for nuclear instrument channels as shown in Fig. 5. The beam hole positions in reactor vessel has Zircaloy re-entrant cans.

Fuel

Dhruva fuel comprises of three major parts, a fuel cluster, an aluminum shielding assembly, and a fuel locking arrangement on top that secures the fuel to the guide tube. All of these fit together to form a fuel assembly of ~ 9 m length. The cluster is made by assembling seven natural uranium fuel pins of ~ 3.0 m length assembled and placed inside aluminum flow tube as shown in Fig. 6. The spacer in the fuel cluster ensures adequate fuel pin separation. The top of the flow tube is connected to aluminum shielding portion by a pin welded to assure positive connection and the top of the aluminum shielding rod is connected to the SS shielding and locking arrangement. The locking arrangement along with backup features keeps the fuel in position within the guide tube. The top and bottom split bulge in the fuel provides adequate flexible support in guide tube bottom and middle position to arrest vibration of the fuel.

Fig. 5 Beam hole arrangement in Dhruva—A plan view (BARC, 2010b).

Operating experience

The reactor has operated with a high availability factor adequately meeting the research and development needs, isotope requirements for healthcare, agriculture and industrial and irradiation studies on materials. The management of heavy water system that serves as coolant, moderator and reflector is one of the major systems from operation and maintenance considerations along with reactor fuel handling. The major incident free operation of these systems along with reliable operation of other systems has been a significant hallmark of Dhruva operations. The aging studies and refurbishment experience at the Cirus reactor facility have provided insights to initiate an aging management and refurbishment program for Dhruva.

Even after the service of more than 30 years while maintaining high availability factors, system modifications and retrofit activities were performed to continue to safely operate Dhruva. These upgrades considered national and international practice and standards, lessons learned from operating experience, changes to regulatory requirements, situations encountered due to obsolescence, additional insights available from periodic safety analysis of the plant, and international events.

In 2017, Dhruva reactor completed over 32 years of operation but some mechanical structural systems needed immediate attention to extend the operation by at least 5 years. Hence, a 2 month planned shutdown was scheduled and major jobs performed during this period were (a) rectify a minor leak in one of the three primary to secondary heat exchangers, (b) a complete overhaul of the fueling machine—a 300 Ton movable and complex mechanical structural system, and (c) replacement of four 900 mm rubber expansion joints in the light water secondary cooling and shutdown cooling header. With these projects completed, it is expected that the Dhruva refurbishment plan can be extended by another 5 years.

Fig. 6 Simplified representation of Dhruva fuel assembly located in reactor guide tube (Agarwal et al., 2006b).

Reactor utilization

Given the international concern regarding under-utilization of research reactor (IAEA, 2016b), the number of irradiation and experimental facilities provided in Dhruva reactor makes this reactor well utilized facility. The isotopes produced in the reactor are used for healthcare, agriculture and industrial applications. The isotope irradiation tray rods enable production of isotopes and regular

Fig. 7 A view of Dhruva reactor hall showing experimental facilities connected to the neutron beam-hole positions (Rao, 2004).

delivery to cater to the market demands. The pneumatic carrier facility of the reactor facilitates short term irradiation of the order ranging from few seconds to a couple of minutes of material for many experimental studies including neutron activation analysis.

The inter-university consortium acts as link between the academic institutions and reactor facility to enables the students and faculties to perform research and experiments using neutron beam facility in the reactor. The 16 neutron beam lines in the reactor and associated setups and instrumentation offer the researcher with source of experiments for R&D in the area of materials, physics, and chemistry research. The neutron activation analysis performed enable understanding the atomic arrangements in the material. There are beam holes for fission fragment studies and neutron tomography towards understanding internal structure of material and components. Apart from this, a provision also exists for engineering experiments in support of new reactor development program. Fig. 7 shows a view of reactor hall showing utilization of beam holes for various scientific and engineering studies.

Final remark and conclusion

Indian experience has been that establishment of research reactor programs is not an option but a necessity for initiating and maintaining nuclear program for societal applications. Dhruva reactor has been utilized effectively and efficiently to support research programs in the area of neutron scattering, activation analysis, material testing and characterization on one hand and isotope production for societal and industrial applications on the other. The safe operation of over 34 years of Dhruva and an accumulated operating experience of research reactors over 140 years testifies to the maintenance of highest standard of safety in design and operations in research reactors at BARC.

Since the Dhruva reactor will be completing 40 years of operation in 2025, as an advance action, the aging studies for reactor systems have been performed and a draft document on refurbishment program has been prepared and undergoing safety reviews. It is expected that after completion of the refurbishment plan, that the reactor life will be extended by another 20 years.

Introduction

History and context

The major nuclear research and development activities in Australia, including the operation of infrastructure and businesses associated with these activities, are conducted by the Australian Nuclear Science and Technology Organization (ANSTO) (<https://www.ansto.gov.au/>), which is an Australian Government organization that has been in existence under its current Act of Parliament (<https://www.legislation.gov.au/Details/C2017C00304>) for a little over 30 years. In practice, the nuclear organization has existed since the mid-1950s as ANSTO was created from the Australian Atomic Energy Commission (AAEC) that came into existence in 1953. The AAEC was transformed into ANSTO in 1987, with the recognition that the basis for its existence had changed from being an organization that conducted research and development focused toward realizing nuclear power for Australia, into an organization that undertook scientific research and development, and commercial activities in a range of non-power nuclear technology applications. Australia has no nuclear power plants and currently has legislation in place preventing these plants from being constructed and operated.

The AAEC owned and operated two research reactors and both were transferred in operational states to ANSTO's ownership in 1987. The first and largest was the HIFAR reactor, which was a UK designed DIDO class reactor that was cooled and moderated by heavy water, had a thermal power of 10 MW, and which operated safely and successfully between 1958 and 2007. HIFAR has been shutdown and is currently in a care and maintenance state. It is planned that HIFAR will be decommissioned in the future. The other research reactor was a 100 kW thermal Argonaut class reactor called MOATA that which operated between 1961 and 1995. MOATA was the first reactor to be decommissioned in Australia in 2009.

ANSTO's current operations are primarily based around large-scale scientific infrastructure that are largely been funded by Government, with the rationale for the funding being scientific research and development, production of radio-isotopes, particularly for health and medicine and the safe and secure management of radioactive wastes. The most important piece of nuclear infrastructure in Australia is the OPAL research reactor, which is multi-purpose by design with its main applications being neutron beams for research and irradiation of many different materials, some of which allow manufacture of radioisotopes for health and medicine. OPAL is a key part of the supply chain for the manufacture of radioisotopes and radiopharmaceuticals for the health sector and other radioisotopes for a number of other industrial and research sectors.

The need for the OPAL reactor was established in the late 1990s when the Australian Government provided funding for a "replacement research reactor" for the HIFAR reactor. The rationale for the new reactor was a continuation of the decades of nuclear based research and development work performed in Australia, a recognition that the facilities available for that work could be upgraded and enhanced with a new facility, and a strategic objective for Australia to remain as an engaged and knowledgeable participant in the international nuclear science and technology community.

Operational history and major milestones

It was decided to build the OPAL reactor (as a replacement to HIFAR) on the same Lucas Heights site as HIFAR to take advantage of the existing site infrastructure. After a rigorous preparation and tender process, in 2000 ANSTO signed a contract with the Argentine company INVAP S.E and its Australian alliance partners, John Holland Construction and Engineering Pty Ltd. and Evans Deakin Industries Limited, for the design, construction and commissioning of OPAL. ANSTO managed the overall design and construction process.

Design and construction were undertaken between 2000 and 2006. The most significant issue that occurred during the construction period was the discovery of two geological features in the excavation zone for the reactor. Construction was halted between April and June 2002 while investigations were undertaken to establish whether the features had significant potential for displacement at or near the ground surface (Pillans, 2003). The outcome of the investigations, which used paleomagnetic dating techniques among other methodologies, were that the faults were older than 7,80,000 years with the three sampled sites yielding interpolated paleomagnetic ages of 2 ± 1 million years, 9 ± 4 million years and 14 ± 8 million years. This meant the faults were classified as “non-capable” and regulatory approval was given to proceed with construction at the reactor site.

An operating license was granted in July 2006, with OPAL achieving first criticality on August 12, 2006, and full operating power in November 2006. The Prime Minister of Australia officially opened OPAL in April 2007.

OPAL is used for:

- Irradiation of target materials to produce radioisotopes for medical and industrial applications;
- Research in the field of materials science using neutron beams and associated instruments;
- Analysis of minerals and samples using neutron activation techniques and delayed neutron activation techniques;
- Irradiation of silicon ingots for use in the manufacture of electronic semiconductor devices.

In July 2007 (<https://www.arpansa.gov.au/sites/default/files/legacy/pubs/regulatory/opal/modifiedfuelstatement160608.pdf>), during a routine reactor shutdown and following a fuel change, the reactor core was examined by video camera as part of the process for returning to power and to ensure correct fuel configuration. During this examination, it was observed that a fuel plate was displaced from its position in a fuel assembly. The subsequent investigation found that several fuel plates had been displaced by varying amounts. The reactor was placed in a safe shutdown condition to undertake detailed investigation and rectification. A design change for the fuel assemblies was proposed and the associated safety case for restarting reactor operations was submitted to the Australian Radiation Protection and Nuclear Safety Agency (ARPANSA) in late 2007. ARPANSA considered the submission and approved restart of OPAL using the new approved fuel assembly design in May 2008.

Since 2008, the combination of full power operational time, excellent reliability, high levels of utilization, particularly for supply of radioisotopes, high quality research publications for neutron beam applications, neutron activation analysis for research and industrial clients and reliable irradiation of more than 50 tonnes of silicon ingots per year, has positioned OPAL as one of the most successful research reactors in the world. The OPAL Reactor aims to operate for 300 days per year at a reliability of over 98%. Between 2010 and 2019 (10 year period), OPAL has operated for 2942 days.

A Periodic Safety Review (PSR) was conducted in 2011 as part of a license condition imposed by ARPANSA. The PSR re-examined the safety of the OPAL reactor taking into consideration operating experience from commissioning and the first 2 years of operation. Apart from submitting the PSR to ARPANSA, ANSTO was also required to seek an international peer review of OPAL. The outcomes from the PSR and an action plan were reviewed and accepted by ARPANSA in 2014 (<https://www.arpansa.gov.au/sites/default/files/legacy/pubs/regulatory/opal/sor-opal2014.pdf>).

Design and operational developments

The major design changes and operational developments instituted at OPAL since it was granted a license in 2006 are summarized below.

i) Fuel Assembly design

In 2008, ARPANSA considered the evidence and assessments provided by ANSTO and other parties on the cause of the fuel plate displacements in 2007 and the proposed rectifications to prevent the displacements from occurring again. The CEO of ARPANSA concluded that the displacement of the fuel plates was a result of a combination of design factors, primarily in that there was no secondary stopper mechanism to prevent movement of fuel plates if a primary fixing failed. A new fuel design with a mechanical stopper incorporated into it was proposed and approved by ARPANSA. OPAL returned to power operation in May 2008, and the new fuel design has been shown to be satisfactory for long term operations.

ii) Heavy Water Isotopic Purification system

Following the discovery of the ingress of light water into the heavy water reflector vessel during the early period of OPAL operation, ANSTO and INVAP proposed to design, construct and operate a heavy water purification system to assist with maintaining the heavy water purity and hence the neutron flux performance of OPAL. The heavy water isotopic purity system was commissioned in 2011 and is operated for approximately 60 days per year to maintain a high level of heavy water purity.

iii) Cold Neutron Source (CNS) system

During the first 5 years of operation, the CNS system operation and reliability was affected by recurring failures of the rotating screws inside the helium gas compressors of the system. After operational and engineering investigations, it was ascertained that the compressors were not being cooled sufficiently and that the subsequent material expansion was causing mechanical failure of the screws. The solution was to redesign the heat exchanger and modify the oil operating temperature used in the helium compressors. This work resulted in significant performance improvements for the CNS system, which since 2013 has been operating reliably.

iv) Maintenance Strategy Optimization

As part of the OPAL operational plan, an asset management program for OPAL has been implemented that utilizes modern engineering asset management methodologies and techniques. A significant component of the OPAL Asset Management program was a project on maintenance strategy optimization. The central aim of the project was to define the optimum mix of maintenance tasks for reactor systems and the use of the resources, both human and engineering based, to achieve the optimum mix. Reliability centered maintenance is the main methodology used and the main components of the maintenance strategy optimization were to specifically identify systems and components that:

- could be maintained via Condition Monitoring by using appropriate surveillances, inspections, testing, monitoring, trending or analysis tasks. Failure modes for these systems and components are addressed with defined potential to failure (P-F) intervals;
- should be overhauled, restored or replaced at fixed time intervals, and which primarily address failure modes that exhibit a predictable wear-out failure pattern;
- could be corrected if an unexpected failure occurs or an expected failure at the end of life which did not penalize performance.

The strategic approach to maintenance has been one of the main contributors to OPAL's excellent operational and reliability performance results.

OPAL utilization

OPAL continues to be utilized at a high level in the main application areas for which it was designed.

i) Radioisotopes (<https://www.world-nuclear.org/information-library/country-profiles/countries-a-f/appendices/australian-research-reactors.aspx>; <https://www.ansto.gov.au/business/products-and-services>)

ANSTO manufacture and supply a range of radiopharmaceuticals, radiochemicals, kits and accessories for use in research, industry and the health sector. The neutron-rich radioisotopes are sourced from OPAL, which has an extensive range of irradiation facilities located in the reflector vessel surrounding the reactor core, with a broad range of neutron fluxes, neutron energies and cooling capabilities available so that a range of different radioisotopes for medicine, industry and research can be produced.

The most extensively used radioisotope in the world for nuclear medicine is Technecium-99 m (Tc-99 m), which is mainly used as diagnostic tool for many different types of patient studies. OPAL was one of the first research reactors in the world to only use low-enriched uranium as the target for neutron irradiation in the production of Molybdenum-99 (Mo-99), which is the parent radioisotope to Tc-99 m. OPAL has 12 irradiation facilities which can be used for Mo-99 production and this capacity, combined with the ANSTO Nuclear Medicine Mo-99 facility, enables ANSTO to supply bulk Mo-99 within Australia and throughout the world, including major exports to the USA and Asia.

Other medical radioisotopes produced by OPAL include, I-131, Sm-153, Cr-51, Y-90 and Lu-177.

ii) Neutron scattering (<https://www.ansto.gov.au/research/facilities/australian-centre-for-neutron-scattering>)

The Australian Centre for Neutron Scattering (ACNS) is a major research facility for neutron science that comprises a suite of neutron instruments that use a range of techniques for scientific investigations in physics, chemistry, materials science, medicine, environmental science and other fields. There are 15 neutron beam instruments at the ACNS, which are classified into four main groups: diffractometers, small-angle spectrometers, imaging and reflectometry instruments and inelastic spectrometers. Most of these instruments have been funded by the Australian Government with some designed and constructed coincident with the design and construction of the OPAL reactor with others funded, designed and constructed over subsequent years as the science program grew. The construction of one instrument (a cold neutron triple-axis spectrometer) was funded by the Taiwanese Ministry of Science and Technology. Another instrument (a BioRef reflectometer) was originally from the Helmholtz Zentrum Berlin and was transferred to the ACNS following the shutdown of the Helmholtz Zentrum Berlin reactor.

Most of the instruments and operating cabins are housed in a Neutron Guide Hall located next to the OPAL reactor. The neutrons from the reactor reach the instruments in the Neutron Guide Hall via various neutron guides that penetrate into the reactor reflector vessel. The Neutron Guide Hall also accommodates sample preparation areas, laboratories and other technical support facilities. Some of the neutron beam instruments are housed in the Reactor Beam Hall which surrounds the concrete reactor block in which the reactor is located. The ACNS also operates three X-ray instruments, a helium polarizing instrument and a physical properties measurement system. Since OPAL commenced operations in 2007, there have been more than 1200 research publications from ACNS and their international and national collaborations.

- iii) Neutron activation analysis (<https://www.ansto.gov.au/research/facilities/opal-multi-purpose-reactor/overview/neutron-activation-analysis-and-neutron>)

There are two major facilities that use neutron activation analysis (NAA) techniques at OPAL. The first is dedicated to research and commercial clients with a wide variety of end uses including environmental science, geoscience and mineralogy, forensics and counter-terrorism, archaeology, agriculture and materials science. NAA is a sensitive method of quantitative multi-elemental analysis where samples are irradiated in the OPAL reflector vessel and after irradiation, the specific activity of radionuclides in the sample can be determined by measuring the energy and intensity of characteristic gamma rays that are emitted. To offer the greatest flexibility to clients and collaborators, both the relative method of standardization and the k_0 -method of standardization have been implemented.

The second facility is dedicated to the Delayed NAA (DNAA) technique for uranium ore assays for clients from the minerals and mining sectors.

- iv) Neutron Transmutation Doping of silicon (<https://www.ansto.gov.au/business/products-and-services>)

There are six vertical irradiation facilities in the OPAL reactor's reflector vessel that are used to irradiate silicon ingots for commercial clients. The irradiation facilities in OPAL have a high 'thermal to fast' neutron ratio (or Cd ratio) that assists with minimizing silicon crystal lattice damage. The facilities have a range of diameters, including the capability to irradiate 8" diameter ingots. OPAL has a high irradiation capacity with more than 50 tonnes being undertaken per annum.

OPAL reactor design

The OPAL Reactor is an open pool type research reactor as shown in **Fig. 1** with an operating power of 20 MW thermal. The fundamental safety objective in the design is the protection of the public, the facility personnel and the environment from exposure to radiation due to its operation. A "defense-in-depth" approach is applied throughout the facility, providing multiple levels of protection against the accidental release of radioactive materials.

The reactor has a compact core, which maximizes the flux of neutrons available for radioisotope production, irradiation services and research. Heavy water is used as the reflector to sustain the nuclear reaction. The heavy water is contained in the Reflector Vessel shown in **Fig. 2** that surrounds the core. The core consists of 16 Fuel Assemblies (FAs) that contain Low Enriched Uranium (LEU). Fission heat is removed by water circulating through coolant channels within the FAs. Reactivity is controlled by five control rods,

Fig. 1 OPAL research reactor pool.

Fig. 2 OPAL research reactor core and reflector vessel.

four of which have neutron-absorber plates inserted into the core in a cross-shaped array and the fifth has a central cruciform shaped absorber plate. The core is thus divided into four portions that each contain four FAs.

The core and the Reflector Vessel are positioned close to the bottom of the 12.6 m deep reactor pool (RPO). The RPO is connected to a Service Pool (SPO) by means of a Transfer Canal. The SPO provides a general working area and enough space to store the spent fuel generated from 10 years of reactor operation.

The Primary Cooling System (PCS) removes the heat from the core by forced upward circulation of water and transfers the heat to the Secondary Cooling System (SCS). A Core Chimney above the Reflector Vessel contains the core coolant before it enters the pump suction line of the PCS piping and provides an additional enclosure for water that protects the core in case of a Loss of Coolant Accident (LOCA).

The RPO inventory is cooled by the Reactor and Service Pool Cooling System (RSPCS), whose main function is the cooling of irradiation rigs. This system also provides long-term pool cooling to the RPO and SPO to extract decay heat.

Fuel design

The reactor core is loaded with plate-type FAs containing uranium silicide powder dispersed in pure aluminum with a maximum uranium density of 4.8 gcm^{-3} . The FAs are square-shaped in cross-section, each with 21 flat fuel plates separated by a channel for coolant flow. Each fuel plate consists of a meat of U_3Si_2 powder (19.75% of U^{235} in weight enrichment) dispersed in an aluminum matrix. The fuel meat is sealed between two aluminum alloy covers (the cladding). The FAs have burnable poison in the form of Cd wires, which are designed to reduce variation in neutron flux over the core life of the FAs. The end box of the FA has an external square section with a circular internal centering hole for coolant flow. The lower end of the inner fuel plates is held by a comb located at the middle of the plates along their width. The side plates of the FA are flat with grooves in their internal faces to allow the positioning and fixing of fuel plates by swaging. The side plates are manufactured in aluminum. There is a handling pin at the top of the FA, attached to the side plates, which allows the fuel to be moved and manipulated with a special handling tool. There are two mechanical stoppers held in place on the side plates and above the fuel plates to provide a secondary mechanism to halt potential movement of the fuel plates.

i) Nuclear physics parameters

The main reactor characteristics and associated core parameters for OPAL are given in [Table 1](#).

OPAL was designed to operate exclusively using LEU fuel and all the uranium targets that are used for Mo^{99} production also use LEU.

Core configuration

The core grid has 16 FA positions in a 4×4 configuration. The core grid is divided into four zones by guide boxes that accommodate five control rod plates in a cross array. The maximum residence time of the FAs in the core is about 180 full power days.

Reactivity control and safety systems

The reactivity control elements consist of Control Rod Plates (CRPs), which are driven by the Control Rod Drives (CRDs) located in the CRD room below the Reactor Pool. The active components of the CRPs are plates made of neutron absorbing material that can regulate the reactor power and shut down the reactor. The CRPs are the core reactivity control part of the First Shutdown System (FSS), which provides the capability to decrease the reactor power level very rapidly as demanded by the First Reactor Protection System (FRPS) or the operators.

Table 1 Main reactor characteristics and core parameters.

<i>General Data</i>	
Type of reactor	Open pool
Nominal thermal power	20 MW
<i>Nucleonic</i>	
<i>Core</i>	
Number of fuel assemblies in equilibrium core array	16
Core dimension	$35 \times 35 \times 61.5$ cm
Net core volume	0.075 m^3
Grid array	4×4
Number of control rods	5
Absorbing material	Hafnium
Core fuel load, average over five Beginning of Cycles (BOCs)	6.23 kg uranium-235
Average at power operation cycle length, reference core	28.8 full power days
Average cycle length, reference core	30.8 days
Maximum power peaking factor, reference core	2.4
<i>Neutronic Data</i>	
Average core thermal flux (average over five BOCs)	$1.07 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$
Average core fast flux (average over five BOCs)	$1.31 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$
Average core thermal flux (average over five EOCs)	$1.18 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$
Average core fast flux (average over five EOCs)	$1.32 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$
Prompt neutron life-time	
BOC, hot/cold ^a	161/165 μsec
EOC, hot/cold ^b	166/171 μsec
Effective delayed neutron fraction (β effective)	
BOC, hot/cold ^a	734/734 μsec
EOC, hot/cold ^b	722/722 μsec
Total reactivity worth (control rods), cold/hot - average over cycle length	19,599/20600 pcm
<i>Nuclear Fuel</i>	
Fuel type	19.75% enriched, U_3Si_2 -Al dispersion fuel
<i>Operational Data</i>	
Full assembly residence time	Approximately 190 full power days
Average discharge burn-up	78,100 MWd/Tn U (46.0%)
<i>Fuel Assembly</i>	
Fuel element type	Plate
Number of fuel elements per fuel assembly	21
Active length	615 mm
Plate thickness	1.35 mm (internal plates) 1.5 mm (external plates)
<i>Thermal-Hydraulics</i>	
<i>Core Thermal Data</i>	
Inlet temperature	Nominal value $37^\circ\text{C} \pm 1^\circ\text{C}$
Average outlet temperature (1900 m ³ /h through the core)	Nominal value $46^\circ\text{C} \pm 1^\circ\text{C}$
Core power density	250 kW/L
<i>Core Hydraulic Data</i>	
Effective coolant flow, minimum	1900 m ³ /h
Coolant velocity in core coolant channel (internal channel)	8.2 m/s
Core pressure drop	205 kPa
<i>RPO Data</i>	
Internal pool diameter	4.5 m
Internal pool height	14.1 m
Internal pool water depth	12.6 m
RPO water inventory	186 m^3

^aAveraged over five BOC.^bAveraged over five EOC.

OPAL has a completely independent Second Shutdown System (SSS) that when operated, partially drains the Reflector Vessel of heavy water. The subsequent neutron leakage from the core is sufficient to shutdown the reactor in a short time. The Second Reactor Protection System (SRPS) controls the SSS and is independent from the FRPS. It also uses diverse technology from that used in the FRPS, thus providing independent and diverse functionality for reactor protection. The SSS will also actuate in circumstances where the FSS fails to actuate.

Reactor control and monitoring

The Reactor Control and Monitoring System (RCMS) is a distributed, computer-based, high-availability system which reads all plant and reactor information and presents it to operators in the reactor control room and other selected workstations. The RCMS enables reactor control, process commands and overall data-management for the operation and monitoring of the facility in normal conditions and to ensure that safety actions are executed under interlock conditions or when limits are exceeded.

From a safety perspective, the FRPS and SRPS have priority over the RCMS and the three systems are functionally, physically and electrically independent.

Primary and secondary cooling system

The Primary Cooling System (PCS) removes the heat from the core during operation at power by forced upward circulation of water and transfers the heat to the Secondary Cooling System (SCS) through the heat exchangers of the Primary Cooling System. The reactor can also be operated in a low-power state where the PCS removes heat from the core via natural circulation and in this case the RPO inventory is enough for safe low power operation.

During forced circulation a core chimney above the Reflector Vessel contains the core coolant before it enters the pump suction line of the PCS piping and provides an additional enclosure for water that protects the core in case of a Loss of Coolant Accident (LOCA).

The RPO inventory is cooled by the Reactor and Service Pool Cooling System (RSPCS), whose main function is the cooling of irradiation rigs. This system also provides long-term pool cooling to the RPO and SPO to extract decay heat. Heat from the RSPCS is transferred to the SCS.

Significant ancillary systems

i) Containment

The reactor containment is the physical barrier that prevents the accidental release of radioactive material from the areas within the containment, namely the RPO and SPO, Reactor Hall, and areas below the RPO that contain RPO water systems and Reflector Vessel heavy water systems, to the environment. The Containment consists of a physical barrier, containment isolation valves, a containment energy removal system and other sub-systems that when initiated, provides automatic closing of valves, heat removal and filtered air circulation for which the containment system is required to provide its protective function.

ii) Electrical

The electrical system is designed to meet demands during operational states and accident conditions. It provides diverse, reliable power sources that are physically and electrically isolated so that any single failure affects only one source of supply and does not propagate to other sources. During normal plant operation, power is delivered from normal electrical supply, and when normal supply is not available, all Safety Category 1 systems receive power from standby diesel generators. Uninterruptible Power Supply (UPS) units also provide reliable uninterruptible power for instrumentation systems to ensure that information is continually available on the plant state.

iii) Radioactive Waste Management

Waste management of radioactive solids includes spent resin handling and storage, the handling and storage of waste from irradiation facilities and the replacement of active components and filters. The Radioactive Liquid Waste Management System (RLWMS) classifies, collects, stores, controls and monitors all liquid waste originating within OPAL. Liquid waste is classified and monitored prior to transfer to the ANSTO site waste treatment facilities. Gaseous emissions from OPAL are monitored by the Air Effluent Monitoring (AEM) System. Any gaseous emission above a preset level will generate signals within the FRPS that will isolate the containment.

iv) Heating, Ventilation and Air Conditioning

Various HVAC Systems are provided for areas outside of the containment for air conditioning, circulation and renewal and to provide the required environment for personnel and equipment.

v) Physical Security System

The physical security system within the facility integrates with protection arrangements at the ANSTO site to provide physical protection to persons, nuclear materials, commercial, scientific and national security information, hardware, software, documentation and operational arrangements. The system also provides protection against unauthorized entry into the Reactor Building.

Experimental support systems

OPAL was designed as a multi-purpose facility with a compact reactor core that has no facilities within the reactor core. All facilities for research and business purposes are either located wholly or partially in the Reflector Vessel that is filled with heavy water and surrounds the reactor core.

Neutron beam facilities

The neutron beam facilities of the OPAL Reactor include:

- i. Cold and thermal neutron source systems.
- ii. Neutron guides for thermal and cold neutrons.
- iii. Neutron beam shutters.
- iv. Auxiliary systems.
- v. Neutron beam instruments.

The neutron guides are used to condition and transport neutrons from the high-density neutron areas located in the Reflector Vessel to the research instruments located in the Reactor Beam Hall and the Neutron Guide Hall.

Other support infrastructure and services include workshops and laboratories, offices, a viewing gallery, cranes, air conditioning and ventilation, electrical supply, communication systems, water supply and drainage and gas supply.

Cold neutron source

The Cold Neutron Source (CNS) consists of a liquid deuterium moderator that operates at a temperature of approximately 20 K. It is located close to the reactor core that increases the neutron yield in the “cold” energy range. Cold Neutrons moderated in this cold fluid are then transported through the neutron guides which transport neutrons to dedicated instruments. The moderator is liquefied and maintained in the liquid state within a natural circulation thermosiphon loop, which has a heat exchanger and a cooling jacket fed with cryogenic helium at 19 K. Both the CNS Refrigeration Cryogenic System and the reactor are capable of operation if the other is shutdown. The CNS is automatically monitored and controlled by a dedicated control and monitoring system that also has a functionally separate protection system designed to protect the CNS.

Thermal neutron sources

The thermal neutron sources comprise two heavy water zones located close to the region of peak thermal flux in the Reflector Vessel. Two neutron beams originate at the thermal neutron source. The neutron spectrum has a temperature in the range from 40 °C to 60 °C. Thermal neutrons are transported through the neutron guides to dedicated instruments.

Irradiation facilities

Radioisotopes are produced by introducing targets into dedicated vertical irradiation positions in the Reflector Vessel. The following irradiation facilities are available at OPAL along with associated laboratories and hot cells.

- a. Bulk Production Irradiation Facilities;
- b. Long Residence Time General Purpose Irradiation Facilities;
- c. Short Residence Time Irradiation Facilities;
- d. Large Volume Irradiation Facilities (currently used for silicon irradiations);
- e. Hot Cells and Auxiliary Facilities;
- f. Interbuilding Pneumatic Transfer System.

The irradiation facilities are controlled and monitored by the previously described RCMS. The range of irradiation facilities offer ability for different sized, targets to be irradiated in different thermal flux energies. Irradiation facilities are also supported by mechanisms to transfer targets into shielded hot cells.

Introduction

At the close of World War II, the United States Federal Government created the Atomic Energy Commission (AEC) to control the peace-time uses of uranium and its fission products. Everyone saw the overwhelming and devastating results of the “Manhattan Project” by the detonation of the first atomic weapon (Code name “Trinity”) in the Jornada del Muerto desert in New Mexico on July 16, 1945. The AEC immediately began to make public scientific information which had heretofore been in the secret category. The purpose being to stimulate peace-time scientific research for the practical application of nuclear reactors for electrical power generation and for the use of fission products for industrial and medical purposes.

Realizing the stimulus to scientific research in many divisions of the University of Missouri which would result from the installation of a nuclear facility at the University, Dean Huber Croft wrote to University of Missouri President Elmer Ellis in October of 1955 suggesting that he may wish to appoint a committee to survey the need for a nuclear reactor at the University. In November of 1955, President Ellis appointed a committee for this purpose consisting of Dean Bent of the Graduate School, Professor Gingrich of the Physics Department, and Professor Brody of the College of Agriculture, with Dean Croft of the College of Engineering as the Chairman (Croft, 1965; Gingrich, 1983).

In June 1956, Senator Jackson introduced a bill in the Senate to provide financial support from the AEC to universities to furnish nuclear facilities. This action was supported by letters to the AEC by Senators Symington and Hennings from Missouri. To indicate the interest of the University in the possibility of a nuclear reactor in Columbia, President Ellis wrote to both Dr. Alan Waterman, Director of the National Science Foundation (NSF), and Admiral Strauss, Chairman of the AEC, in May and December of 1956. This had been preceded by a visit to Dr. Waterman in Washington by President Ellis, Dean Bent and Dean Croft in November 1956.

During 1957, the committee was busy determining estimates of initial costs and annual operating expenses for reactors as well as advantages and disadvantages of the various types of reactors. It was initially recommended that the reactor should be a “research reactor” and not a “training reactor” with a power level of 1000 kW and a neutron flux of at least 10^{13} neutrons $\text{cm}^{-2} \text{s}^{-1}$. Of the kinds available at that time, the CP-5 reactor at Argonne National Laboratory (ANL) and the Massachusetts Institute of Technology (MIT) reactor, which was under construction at the time, were considered. Additionally, different locations near the University were being studied for the reactor site. Later it was also decided that the reactor design should have the flexibility to allow an increase in power at some future date without a major change in the shielding or the building.

On July 7, 1960, the Internuclear Company presented the “Preliminary Design Report” to the University. The design recommended a modified tank-type reactor (pressurized) having an annular core of fuel elements with a light water moderated center test hole, or “flux trap,” having a neutron flux of 2.23×10^{14} neutrons $\text{cm}^{-2} \text{s}^{-1}$ at 5 MWs and 4.51×10^{14} neutrons $\text{cm}^{-2} \text{s}^{-1}$ at 10 MWs. In March of 1961, the “Preliminary Hazards Summary Report” was submitted to the AEC for their review. On November 21, 1961, the AEC issued Construction Permit No. CPRR-68 to The Curators of The University of Missouri authorizing the University to begin construction of a 10 MW research reactor.

On May 28, 1966, Dr. Glenn Seaborg, Chairman of the AEC and 1951 winner of the Nobel Prize in Chemistry, makes a speech titled “The University Research Reactor—A Sign of the Times” at the dedication of the new research reactor at the University of Missouri (United States Atomic Energy Commission, 1966). Following are selected excerpts from Dr. Seaborg’s speech:

"The reactor facility we are dedicating today is an excellent testimonial to both the fruits and promise of the interdisciplinary approach to scientific and technological achievement. Its construction was motivated to a large degree, I am sure, by the contributions it could make to a broad range of activities on this campus and in this area. As a result, we see here not only the reactor itself but a cobalt-60 irradiation unit, chemistry laboratories, an engineering research laboratory, a physics laboratory, and agriculture and medical research laboratories—all facilities which will be essential to those making the fullest use of the reactor itself." ...

"The University of Missouri Research Reactor Facility is an excellent "sign of the times," then, in our present day world of science and technology. The research reactor's ancestral past, and its plans and promise, are interdisciplinary to the highest degree, and also well exemplify the new and dramatic symbiotic relationship between the pure and the applied aspects of science. We see here research and education going hand-in-hand, and we see embodied here the cooperative interest in both of the activities of the State of Missouri and several agencies of the Federal Government. But above all, we see a stimulus and a tool for the continuing pursuit of excellence in which we all have a vital stake." ...

On October 13, 1966, the AEC issued reactor operating license No. R-103 to The Curators of The University of Missouri authorizing the University to operate the 10 MW research reactor at steady-state power levels up to a maximum of 5 MW. The final design of the University of Missouri Research Reactor (MURR) is a pressurized, beryllium and graphite reflected, open pool-type, light water moderated and cooled heterogeneous system with a central flux trap. A flux trap-type reactor is characterized by a thin fuel region adjacent to a good moderator which thermalizes the neutrons and causes the thermal neutron flux to peak in a region.

On October 13, 1966, MURR establishes initial criticality with the 5.2 Kg core. The fuel material at time of initial startup was a uranium-aluminum alloy with each fuel assembly loaded to a maximum of 650 g of ^{235}U . This type of fuel system had performed very reliably in the Materials Test Reactor (MTR) and the Engineering Test Reactor (ETR) as well as in other reactors throughout the world.

On August 13, 1971, in order to reduce the fuel cycle cost and the amount of ^{235}U needed per MWD of energy produced at MURR, the reactor begins the initial use of the 6.2 Kg uranium aluminide (UAl_x) dispersion core with a maximum loading of 775 g of ^{235}U per assembly. The UAl_x dispersion fuel system was developed at Idaho National Laboratory (INL) for the high flux, high power Advanced Test Reactor (ATR) and subsequently used at the MTR and ETR prior to its use at the MURR.

On July 9, 1974, the AEC issues Amendment No. 2 to reactor operating license No. R-103 authorizing the University of Missouri to operate MURR at steady-state power levels up to a maximum of 10 MW. On July 18, 1974, the reactor is upgraded to 10 MW.

On September 1, 1977, MURR starts a 10 MW, 150 h per week operating schedule. Since that day, MURR has continued to operate on this schedule of being online approximately 90% of available hours. No other research or test reactor, domestically or internationally, operates that many hours per year.

MURR continues to be one of safest, most reliable and versatile university-operated research reactors in the world providing critical isotope production capabilities, neutron scattering facilities and a broad range of analytical and irradiation services to the research community and the commercial sector. Scientific programs include research in archaeometry, epidemiology, health physics, human and animal nutrition, nuclear medicine, radiation effects, radioisotope studies, radiotherapy, boron neutron capture therapy and nuclear engineering; and research techniques including neutron activation analysis, neutron and gamma-ray scattering and neutron interferometry.

Nuclear reactor design

Introduction

The University of Missouri Research Reactor (MURR[®]) is a pressurized, reflected, heterogeneous, open pool-type, which is light-water moderated and cooled (Fig. 1). The reactor is designed and licensed to operate at a maximum thermal power level of 10 MW with forced cooling, or up to 50 kW in the natural convection mode. A unique design feature provides an experimental position (flux trap) through the center of the core. A flux trap-type reactor is characterized by a thin fuel region adjacent to a good moderator which thermalizes the neutrons and causes the thermal neutron flux to peak in a region (center test hole) accessible for experiments. A relatively high neutron flux is provided for beamport experiments as well (Foyto et al., 2006).

The reactor core assembly is located eccentrically within a cylindrically shaped, aluminum-lined pool, approximately 10 ft (3.0 m) in diameter and 30 ft (9.1 m) deep. The reactor core consists of three major regions: fuel, control blade, and reflector. The fuel region has a fixed geometry consisting of eight fuel elements having identical physical dimensions placed vertically around an annulus in between two cylindrical reactor pressure vessels. Each fuel assembly is comprised of 24 circumferential plates containing uranium enriched to approximately 93% in the isotope uranium-235 (^{235}U) as the fuel material. The control blade region is an annular gap between the outer pressure vessel and the beryllium reflector, so that no penetration of the pressure vessels is required. Five control blades operate vertically within this gap, controlling reactor power by varying neutron reflection. The control blades are coupled to drive mechanisms by means of a support and guide extension. The drive mechanisms, mounted on the upper bridge over the reactor pool surface, consist of a motor and a reduction gear drive assembly. The reflector region consists of two concentric right circular annuluses surrounding the control blade region. The inner reflector annulus is a 2.71-in. (6.9-cm) thick solid ring of beryllium metal. The outer reflector annulus consists of vertical elements of graphite canned in aluminum, having

Fig. 1 University of Missouri Research Reactor.

a total thickness of 8.89 in. (22.6 cm). The graphite elements are designed to accept the source ends of four radial and two radial-tangential neutron beam tubes.

The fuel region is cooled by a pressurized primary coolant system which, at 10 MW, circulates a nominal 3750 gpm ($0.237 \text{ m}^3 \text{ s}^{-1}$) of light-water coolant through the reactor pressure vessels. The reflector region, the control blade region, and the center test hole are cooled by pool water which is drawn through these regions and circulated through the pool coolant system at a nominal flow rate of 1100 gpm ($0.069 \text{ m}^3 \text{ s}^{-1}$). The heat from the pool and primary coolant systems is transferred to a secondary coolant system by means of separate pool and primary heat exchangers. The heat is then dissipated to the atmosphere through a cooling tower.

The primary design features of the MURR provide the maximum neutron flux to the greatest number of users. The reactor offers the following experimental facilities:

- Center Test Hole (Flux Trap);
- Six Beamports;
- Pneumatic Tube System;
- Graphite Reflector Region Irradiation Positions;
- Bulk Pool Region Irradiation Positions; and
- Thermal Column.

Fuel design

The fuel material at time of initial startup was a uranium-aluminum alloy with each fuel assembly loaded to a maximum of 650 g of ^{235}U . This type of fuel system had performed very reliably in the Materials Test Reactor (MTR) and the Engineering Test Reactor (ETR) at the Idaho National Engineering Laboratory (INEL), as well as in other reactors throughout the world. However, in order to reduce the fuel cycle cost and the amount of ^{235}U needed per MWD of energy produced at the MURR, a conversion was performed in 1971 to switch to a uranium-aluminide (UAl_x) dispersion fuel material with a maximum loading of 775 g of ^{235}U per assembly.

The MURR 775-g fuel element is shown in **Fig. 2** and is a product of the UAl_x dispersion fuel system development. The UAl_x dispersion fuel system was developed at the INEL for the high flux, high power Advanced Test Reactor (ATR) and subsequently

Fig. 2 MURR fuel element.

used at the MTR and ETR prior to its use at the MURR. Several features of the UAl_x dispersion fuel system increase the fuel performance capability in high flux reactors. One of these features is powder dispersion in the fuel matrix causing voidage which will accommodate fission products. The UAl_x structure has exceptional tolerance for fission gas retention and burnable poisons can be readily dispersed in the fuel matrix. Due to the compact core size, the fuel uses high enriched uranium (HEU) to obtain sufficient excess reactivity to be able to operate at 10 MW.

The fuel elements have a radial dimension of 3.21 in. (8.15 cm) as determined from radial length from the inside of the inner roller to the outside of the outer roller and an overall length of 32.5 in. (82.55 cm). Each element is longitudinally-symmetrical with 24 fuel bearing plates. The fuel plates are segments of concentric circles 0.050 in. (0.127 mm) thick separated by a gap of 0.080 in. (0.203 cm). These gaps provide the coolant channels necessary for the removal of the heat generated during the fission process, and for neutron moderation. Additional coolant gaps exist between the innermost fuel plate (No. 1) and the island tube wall (inner pressure vessel), and the outermost fuel plate (No. 24) and the outer pressure vessel wall. These gaps are 0.095 in. (0.241 cm) and 0.075 in. (0.191 cm), respectively. The nominal radius to the innermost plate is 2.77 in. (7.04 cm), and 5.76 in. (14.63 cm) to the outermost plate.

Each fuel plate is fabricated using the "picture frame" method which consists of the fuel compact (fused UAl_x and aluminum powders) encased in a one-piece window-shaped aluminum frame with an aluminum cladding plate welded on both sides, sandwiching the fuel compact. This sandwich is then heated and repeatedly rolled until the fuel plate is 0.050 in. (0.127 cm) thick. This process ensures that a metallurgical bond develops between the fuel material, aluminum powders, and cladding at all interfaces. The fuel meat in each plate is 0.020 in. (0.051 cm) thick. The fuel plates are supported along their vertical edge by slotted aluminum side plates. The fuel plates are permanently fastened into the side plates using a mechanical binding procedure that provides a tensile strength of greater than 150 pounds per linear inch (26.79 kg cm⁻¹) of the side plate joint. This ensures a rigid assembly fully capable of withstanding the hydraulic forces imposed by the primary coolant design velocity of 23 ft s⁻¹ (7.01 m s⁻¹). In fact, fuel assemblies of similar construction have withstood severe hydraulic tests at flow velocities up to 50 ft s⁻¹ (15.24 m sec⁻¹) without distortion, thus indicating an adequate design margin in this regard. The side plates are 31.75 in. (80.65 cm) long by 3.16 in. (8.03 cm) wide and 0.15 in. (0.381 cm) thick.

Tables 1 and 2 provide summaries of the description and specifications of the 775-g MURR fuel elements. A drawing of the MURR fuel element is shown in Fig. 2. Eight (8) such fuel elements comprise the fixed MURR core as shown in Fig. 3. This design

Table 1 Summary sheet for 775-g fuel elements.

Fuel Content (grams ²³⁵ U per element)	775
Type of Fuel	Aluminide-UAl _x mostly UAl ₃ Phase
Fuel Density (grams of ²³⁵ U loaded per cubic centimeter)	1.5–1.6
Boron Content (natural boron per element)	Trace Impurities
K _{eff} (clean core—control blades full out)	1.079
Control Blade Worth (Δk)	0.165
Peak Burnup Density (fissions per cubic centimeter)	< 2.3 × 10 ²¹
Energy per Element at Peak Fission Density (MWD per element)	≈ 180

Weight	≈ 6 Kg

Fig. 3 MURR core layout.

has proven to be reliable with more than 48 years of continuous operation at the MURR, and in other research reactors with no significant failures.

Core loadings

To ensure that the validity of the safety limits is maintained, the reactor core will consist of eight fuel elements. However, operation at power levels up to 100 watts above shutdown power using a core loading of less than eight fuel elements is permitted for the purposes of reactor calibration or multiplication studies. Reactor core loadings are normally comprised of a mixture of eight fuel elements with varying stages of burnup (fissions cm^{-3}). Generally, this mixture consists of two relatively new fuel elements, four fuel elements that are approximately at the “halfway” point, and two fuel elements that are approaching their burnup limit. A mixed core allows the fuel elements to be used to a higher burnup while not exceeding their licensed burnup limit, as specified in the Technical Specifications. **Fig. 3** identifies the fuel element positions and control blade locations in the MURR core.

Fuel conversion

Because of its compact core design (33l), which requires a very high loading density of ^{235}U , MURR could not perform its mission with any previously qualified low-enriched uranium (LEU) fuels. However, in 2006 with the prospect of the National Nuclear Security Administration (NNSA) Global Threat Reduction Initiative Reactor Conversion Program validating the performance of U-10Mo monolithic LEU foil fuels, MURR began actively collaborating with what is currently the NNSA Material Management and Minimization (M3) Office’s Reactor Conversion Program, along with four other U.S. high-performance research and test reactors that use HEU fuel, to find a suitable LEU fuel replacement. It was concluded that the proposed LEU fuel assembly design, in conjunction with an increase in power level from 10 to 12 MW_{th} , will (1) maintain safety margins during steady-state and transient conditions, (2) allow operating fuel cycle lengths to be maintained for efficient and effective use of the facility, and (3) preserve an acceptable level and spectrum of key neutron fluxes to meet the scientific mission of the facility. Current projected conversion date is July 2028 (Foyto et al., 2017).

Control blades and control system

The reactivity and power of the reactor are controlled by five neutron-absorbing control blades, which are all located external to the pressure vessels. Each control blade is coupled to a control blade drive mechanism by means of a support and guide extension (offset mechanism). Four of the control blades, referred to as the shim blades, are used for coarse adjustments to the neutron density within the reactor core. The fifth control blade is a regulating blade. The low reactivity worth of this blade allows for very fine adjustments in the neutron density in order to maintain the reactor at the desired power level.

The shim blades are constructed of formed BORAL[®] plate which is, by weight, nominally 50% boron carbide and 50% aluminum. The boron carbide-aluminum mixture is clad with 0.0375 in. (0.09525 cm) of aluminum-alloy 1100 for a nominal blade thickness of 0.175 in. (0.4445 cm). All four sides of the blades have a 0.25-in. (0.635 cm) aluminum frame where the blade thickness is 0.25 in. (0.635 cm). The active length of the neutron absorbing material is 34 in. (86.35 cm), and the overall blade length is approximately 40 in. (101.6 cm). The upper 6 in. (15.25 cm) of the shim blade is a 0.25-in. (0.635 cm) thick aluminum mounting plate that is curved to the shape of the blade. Each shim blade occupies approximately 72 degrees of a circular arc around the pressure vessel.

The regulating blade is constructed of stainless steel. The blade has an overall length of approximately 30 in. (76.2 cm) and occupies approximately 18 degrees of the circular arc.

The shim blades are positioned by four control blade drive mechanisms mounted on the upper bridge over the reactor pool surface. Each control blade drive mechanism consists of a 0.02-HP, 115-V, one-amp, single-phase, 60-cycle motor connected to a lead screw assembly through a reduction gear box and overload clutch. The lead screw assembly converts the rotating motion of the drive motor to the linear motion of the control blades. The overload clutch allows slippage of the lead screw should a shim blade become bound within the control gap. A ball nut coupled directly to a drive tube is driven inward and outward by the lead screw. Connected to the bottom end of the drive tube is an electromagnet which engages a cadmium-plated carbon steel anvil attached above the water level to the end of a lift-rod assembly. The lift-rod assembly allows the positioning of a shim blade through a support and guiding mechanism (offset mechanism) mounted on a pedestal attached to the reflector tank. Limit switches mounted on each control blade drive mechanism stop the drive motor at the top and bottom of travel. These limit switches also provide indication on the reactor control console that the drive mechanism is either in the full-in or full-out position.

The shim blade can be withdrawn when the electromagnet is energized. When the reactor is scrammed, the electromagnet is de-energized, releasing the anvil, and allowing the shim blade and lift-rod assembly to drop. Loss of electrical power to the control blade system results in a reactor scram and safe shut down of the reactor. A dash pot assembly cushions the fall of the shim blade during the final 20% of travel.

The regulating blade is positioned by a control blade drive mechanism similar to the ones used for the shim blades with a few exceptions. A scram signal does not insert the regulating blade; therefore, an electromagnet and an anvil are not required. The lift-rod assembly is pinned directly to the drive tube. Also, the regulating blade is driven at a faster speed than the shim blades, requiring a different reduction gear box.

The reactor is operated from the reactor control console in either of two control modes: manual or automatic. Manual control is used for reactor start-up, changes in power level, and steady-state operation for short periods of time. Automatic control is selected only after a minimum power level has been attained and is used for long term steady-state operation.

Control blade movements, interlocks and bypasses, and control modes are managed by the Rod Control System. The Rod Control System is a relay and switch logic system used to prohibit accidental or incorrect operation which could result in an unsafe condition. Rod position indication is determined and displayed in the reactor control room by a system of microcomputer controlled instruments. The system consists of a central control chassis and a remote display unit which provides the reactor operator with control rod height in inches.

The controlling parameter for automatic operation of the Rod Control System is the neutron flux monitored by a compensated ion chamber (CIC). The neutron flux is essentially proportional to the reactor power level. The pulse signal generated by the CIC is routed to the wide range neutron flux monitor located in the reactor control room. An output signal produced by the wide range signal processor drawer is then routed to a solid state servo amplifier. This output signal voltage is proportional to that of the input signal generated by the CIC.

The servo amplifier is mounted on the control room instrument panel. The servo amplifier automatically controls the power level of the reactor by comparing the output signal from the wide range signal processor drawer with the power schedule setting. The power schedule set point is adjusted by a spring return switch and displayed on a meter mounted on the reactor control console. The output from the signal processor drawer is a 0 to +10 VDC signal, corresponding to 0 to 125% reactor power level (+8.0 VDC = 100% power). The output from the power schedule potentiometer is a 0 to -10 VDC signal depending on the setting. This $\pm$ voltage window represents the $\pm$ control sensitivity of the servo amplifier. If a mismatch does exist, a positive or negative output signal is generated and sent to the relay-controlled drive motor of the regulating rod drive mechanism, which repositions the regulating blade, stepwise, in a direction which minimizes the discrepancy between the power schedule setting and the actual power level.

The Reactor Scram System consists of the electronic circuitry which can initiate the instantaneous drop of the reactor control blades (reactor scram) by interrupting power to their electromagnets should a monitored parameter (power level, temperature, flow rate, etc.) exceed a predetermined value. A reactor scram may also be initiated manually by depressing a push button on the reactor control console.

The protection channels and protective responses are sufficient to ensure that no safety limit, limiting safety system settings, or Reactor Scram System limiting condition for operation will be exceeded. The system design ensures that the design bases can be achieved, and that the system can be readily tested and maintained in the designed operating condition. Sufficient safety system isolation and independence is provided to avoid malfunctions or failures caused by other systems. The Reactor Scram System reasonably achieves safe reactor shutdown in the event of a single random malfunction within the system. System operation prevents or mitigates hazards to the reactor or the escape of radiation, so that the full range of normal operations poses no undue radiological risk to the health and safety of the public, the facility staff, or the environment.

The Rod Run-In System is designed to initiate the automatic insertion of the shim blades at a controlled rate of 0.085 cm s^{-1} (2 in. per minute) should a monitored parameter exceed a predetermined value. This system is not part of the Reactor Scram System; however, it does provide a protective function by introducing shim blade insertion to terminate a transient prior to actuating a Reactor Scram System set point trip. The Rod Run-In System also inserts the control rod drive mechanisms in the event of a scram condition. A rod run-in may be initiated manually by depressing a push button on the reactor control console.

Neutron moderator and reflector

In addition to removing the heat generated from the fission process, coolants from the primary and pool systems also serve as the neutron moderator. Neutron reflection is provided by two concentric right circular annuli surrounding the reactor pressure vessels. The reflector materials have a rigid structure that retains size and shape, and supports all projected forces and weights. The inner reflector annulus is a 2.71-in. (6.88 cm) thick solid ring of beryllium metal which forms the outer wall of the control blade gap. Additional reflection is provided by an outer reflector annulus consisting of canned vertical elements of graphite having a total thickness of 8.89 in. (22.58 cm). Each graphite element is protected from water penetration by a leak-tight welded aluminum can. The graphite elements are designed to allow horizontal penetration of the beam tubes perpendicular to the beryllium reflector ring. The overall height of the graphite reflector region is 36 in. (91.44 cm), and it is centered vertically with respect to the fueled region. The height of the beryllium reflector is 37 in. (93.98 cm) and it extends 1 in. (2.54 cm) below the graphite reflector.

Reactor coolant systems

MURR utilizes three coolant systems: Primary, Pool, and Secondary. The primary and pool coolant systems are designed for three (3) modes of operation:

- (1) Mode I—At power levels of up to 10 MW with the primary coolant system pressurized and at a flow rate of approximately 3800 gpm ($0.240 \text{ m}^3 \text{ s}^{-1}$), and a pool coolant flow rate of approximately 1200 gpm ($0.0757 \text{ m}^3 \text{ s}^{-1}$); used when all heat exchange and pumping capacity is available;
- (2) Mode II—At power levels of up to 5 MW with the primary coolant system pressurized and at a flow rate of approximately 1900 gpm ($0.120 \text{ m}^3 \text{ s}^{-1}$), and a pool coolant flow rate of approximately 600 gpm ($0.0379 \text{ m}^3 \text{ s}^{-1}$); utilizing only half the design heat exchange and pumping capacity available; being the maximum operating power level at the time of initial startup; and
- (3) Mode III—At power levels of up to 50 kW with the primary coolant system open to the reactor pool, the reactor pressure vessel head removed, the flanged port open, and the pool water level at the elevation of either the upper or lower reactor bridge; used for core flux calibrations following the loading of a new core, or after a fuel rearrangement.

Heat from the primary and pool coolant systems is transferred to the secondary coolant system by means of heat exchangers. This heat is then dissipated to the atmosphere through a cooling tower. Auxiliary systems which support the three principal reactor coolant systems are also discussed in this chapter.

Experimental facilities and utilization

Introduction

The experiment program at MURR provides a broad range of analytical, radiographic, and irradiation services for use by the research community and the commercial sector. Experiments conducted at the MURR are subdivided into two general classifications: (1) neutron beam, and (2) neutron irradiation and isotope production. The neutron beam experiments are those research projects which utilize one of the beamports. The neutron irradiation and isotope production experimental facilities include the center test hole, the graphite reflector region, the pneumatic tube system, and in-pool locations external to the graphite reflector (bulk pool). Some of the irradiation services provided by these experimental facilities include isotope production for the development of radiopharmaceuticals, neutron activation analysis (e.g., archeological samples), and transmutation doping of silicon. The beamports are primarily used for neutron scattering useful in determining the structure of solids and liquids.

The principal purpose of the MURR is to provide neutrons to the experimental facilities, and the design effort has been directed toward accomplishing this end. In order to accomplish the goals of the experiment program, the design of the reactor and the experimental facilities must be rather unique, but must also emphasize safety as a paramount concern. This latter requirement further dictates design criteria. A major safety feature of the reactor can be found in the design of the beryllium reflector, which effectively decouples the reactor core from experiment variations in the beamports, bulk pool and graphite reflector irradiation positions, the pneumatic tube system, and the thermal column. The only experimental facility not neutronically decoupled from the reactor in this manner is the center test hole (flux trap). However, this experimental facility is subject to a high degree of administrative control as discussed in the following section.

Center test hole

The Center Test Hole (Flux Trap) is that portion of the reactor through the center of the core which is bounded by a 4.5-in. (11.43-cm) inside diameter inner pressure vessel (island tube) and which extends 15 in. (38.1 cm) above and below the core centerline. A specially-designed test hole canister is inserted into this region of peak thermal flux ($6 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$) for the purpose of material irradiations.

Beamports

The reactor is designed to accommodate six (6) horizontal beamports. These hollow tubes channel neutrons and gamma radiation from the reactor core with minimal scattering and attenuation between the beryllium reflector and the experiment equipment. Each beamport designation, size, elevation, and description is shown in [Table 1](#).

[Fig. 4](#) provides the current beamport layout and associated instruments.

Each beamport assembly consists of three major components: a fixed beamport liner, a removable beamport liner (beam tube), and typically, a removable collimator liner. The fixed beamport liner provided the necessary form work during the pouring of the biological shield, therefore it is the only component of the beamport assembly which is in direct contact with the magnetite concrete of the biological shield. The fixed liner is integrally welded to the reactor pool liner and serves as an extension of the reactor pool into the beamport vestibule. The fixed beamport liner allows penetration of the removable liner through the biological shield from the recessed vestibule inward, penetrating the graphite reflector region and terminating adjacent to the beryllium reflector. The portion of the beam tube within the graphite reflector region is cooled by pool water flowing downward through the gaps between the graphite reflector elements and around the beam tube. When the removable liner is fully inserted, a gap exists between it and the fixed liner. A $\frac{1}{2}$ -inch line, which penetrates the fixed beamport liner, returns water from the pool skimmer system into this area and then back into the reactor pool volume. This flow path prevents the stagnation of pool water in the beamport, helping minimize corrosion to the fixed and removable liners. The removable liner is attached to the fixed liner by means of a bolt ring located in the recessed vestibule. A packing gland assembly seals the removable liner to the fixed liner. Typically, a removable collimator liner is located within the removable beamport liner. The removable beamport liner provides a path for the neutron beam to travel prior to entering the removable collimator liner, where the beam is further shaped and defined by the collimator for the experiment equipment. The collimators are designed to accept different neutron filters. Crystal-sapphire and silicon are the predominant choices for filters utilized in the MURR neutron scattering experiment program. The removable collimator liner is attached and sealed to the removable beamport liner similarly to the way the removable liner is attached and sealed to the fixed liner. This allows filling the removable beamport liner with helium if a neutron beam is to be accessed, or demineralized water if not.

Pneumatic tube system

The Pneumatic Tube (P-Tube) System is designed to quickly transfer individual samples into and out of the graphite reflector region of the reactor core assembly. The samples are placed in small high density polyethylene sample carriers, or "rabbits," and

Fig. 4 MURR beamport layout.

transported at velocities of 30 to 45 ft per second ($9.1\text{--}13.7\text{ m s}^{-1}$) from designated laboratories into a region of relatively high thermal flux (approximately $1 \times 10^{14}\text{ n cm}^{-2}\text{ s}^{-1}$) for the purpose of material irradiation.

Introduction

The Massachusetts Institute of Technology Research Reactor (MITR) is located on MIT campus in Cambridge, Massachusetts. The first reactor, MITR-I, started construction in June 1956 and achieved criticality in July 1958. The MITR-I was a heavy-water cooled and moderated tank-type reactor using MTR-type fuel elements. It was one of the first university research reactors built on university campus to accomplish missions in education, training, nuclear science and technology, and fundamental and applied research such as metallurgy, radiochemistry, geology, and medicine. Following a year of low power tests after initial criticality, the reactor began a routine three-shift schedule at a power level of 1 MW in July 1959 with the exception of weekend shutdowns for maintenance and for refueling and experiments. In July 1961, the power was raised to 2 MW, and in November 1965 to 5 MW, the power level for which the MITR-I was designed ([MITR Staff, 1968](#)).

The MITR-I was shut down in 1974 for dismantling, construction and pre-operational testing until the second reactor, MITR-II, went critical in August 1975. The MITR-II is a light-water cooled and moderated, heavy water reflected tank-type reactor, located in the same shielding and containment structure as the MITR-I. It was designed to operate at 5 MW with a new finned aluminum clad MTR-type fuel element design in a compact hexagonal core housing to increase neutron flux, improve fuel economy and reduce personnel dose during refueling ([Allen, 1976](#)).

In July 1999, a formal application was submitted to The U.S. Nuclear Regulatory Commission (NRC) to relicense the reactor for an additional 20 years and to upgrade the power level from 5 to 6 MW with the existing fuel design, reactor operation conditions, and containment structures. The NRC issued a license renewal along with approval for 6 MW operation in November 2010 ([MITR Staff, 2011](#)). In order to accomplish the transition to higher operating power, major improvements were made since the late 1990s to reactor cooling systems including primary coolant pumps, heat exchangers and cooling towers as well as modern instrumentation.

The MITR has contributed to many research projects through the years, such as production of medical isotopes, closed-loop digital control of spacecraft and terrestrial reactors; boron neutron capture therapy for the treatment of cancer; material studies for advanced reactors; and neutron activation analysis for the study of environmental contaminants.

The MITR currently operates at its licensed power continuously up to 10 weeks per cycle and a nominal 3-week outage for refueling and maintenance. It has one of the strongest in-pile irradiation programs on a university campus, supporting experimental studies in the areas of advanced nuclear fuel, materials and instrumentation which are necessary for both existing and advanced power reactors. With renewed interest in developing advanced nuclear power systems, many using novel materials and advanced forms of fuels, facilities such as the MITR are needed to test material and fuel behavior in a variety of radiation environments. The MITR is one of the best suited research reactors for carrying out such studies because of its relatively high-power density (similar to a light water reactor), the capability to control chemistry and thermal conditions to reflect prototypic conditions, its easy-access geometric configuration, and being located on a university campus that offers easy access to researchers and students.

The MITR is integrated into national programs through various Department of Energy's initiatives, such as the Nuclear Science User Facilities (NSUF) ([NSUF, n.d.](#)), and through collaboration with national laboratories, industry, and other universities. Research and service areas currently supported by the facility include:

- Experimental infrastructure to support the US initiatives to design and build the next generation of nuclear reactors, such as Molten Salt Reactors and High-Temperature Gas Reactors;
- Advanced nuclear materials and fuel research,
- Trace element analysis, isotope production, and irradiation services,

- Neutron transmutation doping of silicon,
- Neutron scattering, and
- Design, licensing, and planning for conversion from Highly Enriched Uranium (HEU) fuel to a high-density Low Enriched Uranium (LEU) fuel.

MITR reactor design

The MITR operates at 6 MW with light water primary coolant temperature around 50 °C at atmospheric pressure, and nominal flow rate of 125 kg/s (2000 gpm). Secondary coolant transfers the fission power from the primary cooling system, heavy water and graphite reflector, and auxiliary cooling systems and rejects the heat to atmosphere through forced draft cooling tower.

a. Fuel Design

The MITR utilizes flat, plate-type, finned, aluminum-clad fuel elements with highly enriched uranium (HEU). Each fuel element consists of 15 identical fuel plates. The fuel plates are assembled between two grooved side plates. The fuel plates are 0.20 cm thick with longitudinally-milled fins on both sides to increase the heat transfer surface area. The fuel plates are 6.48 cm wide, 58.42 cm long and are spaced 0.40 cm apart to form 14 cooling water channels 0.20 cm wide fin-to-fin. The fins are 0.025 cm high and 0.025 cm wide separated by 0.025 cm wide grooves. Within an element, the spacing between the fuel plates is maintained by the grooves in the side plates. Between elements, end nozzles which are designed to provide structural rigidity for the element maintain the necessary spacing. The fuel elements are rhombic in shape with a perpendicular distance between the flats of 6.03 cm. The overall length, including the end nozzles, is 66.68 cm. Each element has same nozzles at both ends, thereby allowing it to fit into the lower grid plate and to mate with the upper hold-down grid. The fuel element design is both radially and axially symmetric so that they can be both rotated and inverted in order to equalize the effect of flux peaks on burnup.

Each fuel element contains about 510 g of U-235. The amount of U-235 is evenly distributed among each fuel plate. Each plate contains fuel meat which is approximately 93% enriched uranium in the form of a UAl_x cermet. The fuel meat is 55.88 cm to 57.79 cm long, 5.29 cm wide, and 0.08 cm thick and clad with 6061 aluminum alloy. The nominal thickness of the cladding is 0.038 cm, not including the fin height. The UAl_x powder sintering process results in a final product that is at less than theoretical density, specifically the void fraction is between 4% and 7%. This provides space for fission product gases and hence prevents fuel plate swelling. The MITR fuel elements do not contain any burnable poisons or moderating materials.

b. MITR Core Design

The reactor core consists of 27 positions, up to 24 positions are filled with fuel elements. The remaining three positions are filled with either a solid aluminum “dummy” element or an in-core experiment. The MITR uses six coarse-control shim blades and one fine-control regulating rod located at the core peripheral to adjust reactivity during reactor operation. The core map and location of these control elements is shown in Fig. 1 below.

Fig. 1 Schematic of the MITR core showing 27 fuel positions, shim blades, and regulating rod.

c. Reactivity Control and Safety Systems

There are six identical shim blades arranged symmetrically with respect to the core. These blades are contained within the light-water core tank and occupy the space between the outermost ring of fuel, the C-Ring, and the core-housing wall. The full range of travel is such that the tip of the blade is never withdrawn from its guide slot. The reactor shutdown margin requirement is such that it is possible to shut the reactor down from its most reactive state with the most reactive blade (and also the regulating rod) in the full-out position. In addition, the reactor can operate with only five blades being functional provided that the remaining one is at or above the average height of the functional ones. Thus, only five are needed to shut down and to operate the reactor. Each blade can be operated independently of the others. Another reactor protection is further provided by the capability to dump the heavy water reflector and thereby shut down the reactor.

The shim blades, which measure 77.8 cm by 17.78 cm by 0.76 cm, are made from 1.1% natural boron impregnated stainless steel. Each blade consists of two 0.32 cm-thick plates separated by spacers so that a 0.13 cm gap exists in the lower 59.36 cm of the blade. This gap, which allows water to circulate between the plates, provides cooling and helps to prevent warping because of radiation damage. An aluminum connecting arm is attached to the guide rod of each shim blade assembly. Affixed to this connecting arm is an armature that is plated with corrosion-resistant material such as nickel or chrome. The shim blade assemblies move up or down at a constant speed of 0.18 cm s^{-1} . The maximum travel of the shim blades is 53.34 cm. When the current to the electromagnet on the drive mechanism is cut off, the armature is released thereby dropping the shim blade assembly by gravity.

There is one regulating rod for fine reactivity control and is connected to automatic controller. It is located exterior to the core in one of the small circular holes at the corner of the core support housing. The regulating rod consists of an extension and an absorber section. The absorber section is 63.18 cm long with a 2.22 cm outer diameter. The bottom 45.7 cm of the absorber section consists of an inner aluminum rod, a cadmium wrap, and an outer aluminum clad. The mechanism for moving the regulating rod in or out is similar to the shim blade mechanisms. The travel speed of the regulating rod is 0.18 cm s^{-1} . The regulating rod mechanism differs from the shim blade mechanism in that there is no electromagnet assembly. Hence, the regulating rod does not drop into the core upon automatic scram. Rather, a scram signal causes it to be driven inwards at its normal speed.

d. Reactor Tanks

The reactor core, the light-water coolant and moderator, the heavy water reflector and its helium cover gas, and the control devices are all contained within two concentric tanks. These are the light-water core tank and the heavy-water reflector tank. All penetrations through the light-water tank are above the core. All penetrations that are capable of creating a siphon that could drain the tank are equipped with a siphon-break to prevent that occurrence. Both tanks are designed against failure that could cause loss of integrity, and both would have to fail in order for the core to be uncovered. A pipe break or a single tank failure could not result in such a scenario.

The light-water core tank was manufactured and installed in 1974. The MITR's core shroud and flow guide, which are attached to the core tank and the core support housing respectively, are also described here. The core tank contains more than 2700 l of light water coolant which serves as the heat sink for fuel decay cooling. There are four natural convection valves located at the bottom of the core tank outside the core shroud. These valves and two anti-siphon valves open upon loss of primary coolant flow and allow natural circulation flow in the core tank to remove decay power from the core. Fig. 2 are pictures of the hexagonal compact core with 24 fuel elements installed, and top view of the light-water core tank. Fig. 3 is a cross-sectional view of the MITR showing the core tank, heavy water reflector tank, and graphite reflector.

e. Reactor Coolant Systems

The MITR's primary coolant is light water. The purpose of the primary coolant system is to remove the heat generated in the core by fission, to moderate neutrons, to provide shielding for the reactor top, to serve as a reservoir of coolant for possible emergencies, and to act as a barrier that would prevent the release of fission products in the event of multiple failures. The system, which consists of pumps and heat exchangers as well as valves and piping, is located within the reactor containment building. A storage tank allows for the expansion and contraction of the coolant that results from temperature variations. An air purge that is drawn through the space between the surface of the coolant and the underside of the core tank's lid precludes the buildup of any radiolytic gases associated with reactor operation. The air purge system automatically isolates if abnormal radiation levels are detected by radiation monitors. Hence, the primary coolant system operates at closed to the atmospheric pressure, and it serves as one of three barriers to fission product release. The MITR is normally operated under forced convection. However, the natural convection mode of operation is also possible at low power levels ($< 100 \text{ kW}$).

Beyond the core region, gamma heating is also deposited in the heavy water and the graphite reflectors. This energy is removed by the reflector coolant and shield coolant systems, respectively. Each system has its own dedicated pump, heat exchanger, and cleanup system. The secondary coolant system also uses light water. It transfers heat from the primary, reflector, and shield coolant systems, and it discharges the heat to the atmosphere via the cooling towers.

The MITR has operated at its licensed power for at least 90 h per week during the 1970s through 1990s. In 1990s through late 2000s, it has operated 24 h per day, 7 days per week with a shutdown of a few days per month for maintenance, test and calibration, refueling, etc. Since 2010s after receiving 6 MW operating license, the MITR operates with quarterly cycles, continuously up to 10 weeks per cycle and a nominal three-week outage for maintenance and refueling, in order to support in-pile materials and instrumentation tests. The power history of the reactor maintains a strong photo-neutron source generated from decay gammas reaction

Fig. 2 (A) MITR core with Cherenkov radiation (B) Top view of the MITR core tank.

with the deuterium in the heavy water reflector tank. Accordingly, there is no need for an installed neutron source with the exception of the initial fresh fuel startups as was performed in 1958 and 1975 and may be required for initial startup of the LEU fuel when conversion occurs in the future (Hu et al., 2020).

Experimental facilities

The MIT Nuclear Reactor Laboratory (NRL), an interdepartmental laboratory which operates the MITR, has an extensive array of facilities for performing neutron and gamma irradiations, studying neutron physics, and instruments for examining radioactive materials. A comprehensive description of the irradiation facilities which contains pneumatic tubes, beam ports, in-pile irradiation facilities, associated neutron activation analysis laboratory, hot cells and post-irradiation examination instruments can be found online ([MIT Nuclear Reactor Laboratory, n.d.](#)). A summary of the MITR's experimental facilities is given below.

In-Core irradiation facilities

The MITR has the capability to perform a wide range of experiments in the reactor core which has neutron flux and energy spectrum similar to a light water power reactor. In-core experimental facilities are not permanently installed in the reactor. Facilities that can be reused are stored in hot cells or shielded locations in the reactors containment building. A brief list of the types of facilities that are available includes:

- An inert gas-filled irradiation tube (ICSA) for sample capsule irradiation at $<900^{\circ}\text{C}$ (instrumented/lead-out or un-instrumented),
- Forced-circulation coolant loops that replicate conditions in both pressurized and boiling water reactors (up to 300°C and 10 MPa),
- High temperature ($>900^{\circ}\text{C}$) irradiation facility for materials irradiations in inert gas (He/Ne mixture),
- Custom, dedicated facilities for irradiations in unique conditions (e.g., molten fluoride salts).

Fig. 3 Cross-sectional view of the MITR.

Beam ports and pneumatic tubes

The MITR has 11 neutron beam ports surrounding the reactor. The biological shield ranges from 7.62 to 30.18 cm (3" to 12") in diameter. There are also two tangential through tubes that pass near the reactor heavy water reflector. Two systems are available to perform neutron irradiations on small samples by pneumatically inserting them into positions near the MITR core, a 5.08 cm (2") high flux pneumatic tube, and a 2.54 cm (1") intermediate flux pneumatic tube.

Neutron scattering

The MITR has two neutron scattering facilities: a Triple-axis diffractometer equipped with Pyrolytic Graphite (PG) monochromator, PG analyzer, He-3 monitors, and detector and standard collimators, slits, and PG filters, and a neutron optics test station with polychromatic neutron beam.

Time-of-flight experimental facility

This facility can be operated locally or remotely over the internet for student experiments in neutron energy distributions, attenuation, and scattering. Also available for neutron detector testing or cross-section measurements.

Post-irradiation examination (PIE) facilities

The MITR has a wide range of facilities that are useful for handling and examination of highly radioactive materials. These include:

- Hot cells and for remote handling of irradiated components and materials,
- Hot sample preparation facilities,
- Helium-filled glove box with high-temperature furnace and gamma shielding
- Electron microscopy facilities,
- Access to electron microscopy facilities can be arranged for irradiated samples.

Vital nuclear engineering research

The in-pile irradiation experiments at the MITR is an integral part of the Department of Energy Office of Nuclear Energy's effort to improve current generation nuclear reactors and develop new reactor technologies with improved economics and safety. It is the only university research reactor engaged in testing significant irradiation damage levels in environments representative of commercial power reactors, and is an excellent complement to national laboratory test reactors. Current irradiation experiments cover four major areas:

a. Accident tolerant fuel development

Developing accident tolerant fuel became a focal point for the nuclear industry following the 2011 earthquake and tsunami that led to the Fukushima nuclear accident in Japan. This fuel would be able to withstand "beyond design basis" accidents without releasing radioactivity into the environment. At most commercial reactors, nuclear fuel cladding is currently made from a metallic alloy of zirconium called Zircaloy™. Ceramic composite material, however, is known for having better high temperature strength and corrosion resistance compared to Zircaloy™ and is being investigated as an alternate cladding. The MITR carried out one of the first irradiation tests in high temperature, high pressure water of a ceramic composite material based on silicon carbide as an alternative to Zircaloy™. These early results demonstrated that testing materials in an irradiation environment is crucial to understanding their behavior and the program has played a major role in developing a viable ceramic composite cladding.

b. Advanced instrumentation testing

The extreme environment of a nuclear power reactor, or recreated environment in a research or test reactor, proves challenging for instrumentation. Instrumentation, such as sensors of various types, however, are vital to fully exploit expensive irradiation experiments in a reactor. They are used to characterize the test environment (temperature, pressure, radiation intensity and various chemical parameters) and to measure the response of the test materials in real time. The alternative to real time measurements is the periodic removal of samples for testing, which is expensive, time-consuming, may affect the parameters being measured and gives no information about the changes that occur between removals. Sensors capable of withstanding extreme nuclear environments also have applications in operating power reactors to monitor normal and accident conditions. The MITR has an ongoing program of in-core testing of advanced ultrasonic and fiber-optic sensors, as well as more traditional thermocouples optimized for nuclear use at high temperatures. In-core irradiation tests have also included detectors for neutron and gamma irradiation, measurements of electrochemical corrosion potential (an important parameter for understanding the corrosion and cracking of metals in water or molten salt coolants). A specialized sensor for measuring the crack growth in a stressed sample in-core was adapted from Halden reactor and successfully demonstrated in the MITR.

c. Molten Salt Reactor (MSR) research

A promising MSR design, Fluoride salt-cooled High-temperature Reactor (FHR) utilizes coated particle fuel, was shown to be safe and economical. In addition to generating electricity, it would also be able to operate at temperatures high enough to provide process heat for industrial applications. The design is based on combining several technologies: the fuel from high temperature gas reactors, modern gas turbines for power production, and a molten lithium fluoride/beryllium fluoride salt (flibe) as the coolant. Many aspects of the technology have been previously tested, but many technical challenges remain to demonstrate a complete reactor. Understanding the behavior of the molten flibe salt and its interaction with the other reactor components under irradiation is vital. Four irradiations of flibe salt at 650–700 °C have been carried out at the MITR since 2013 to advance the technologies needed for MSR development ([Dolan et al., in press](#)). These were the first irradiations of flibe since the MSR Experiment at Oak Ridge National Laboratory in the 1960s.

d. Nuclear fuel testing

Advances in nuclear fuel design to improve safety or efficiency require extensive testing to reach the point where they can be demonstrated and more widely adopted in operating power reactors. In the U.S., in-core testing of actual fuel materials was once only possible in test reactors at national labs. The MITR was licensed in 2003 to test actual fuel materials in its core, allowing new fuel concepts to be tested on a small scale and at significantly reduced cost and shorter turnaround compared to larger scale experiments at larger test reactors. Two types of fuel samples have been tested. The first tested the impact of providing an additional coolant channel on the inside of a nuclear fuel rod to reduce the temperature of the fuel and improve safety. The second tested the response of a different form of uranium fuel, which is a better heat conductor than the fuel typically used in power reactors. The improved conductivity reduces the temperature of the fuel and improves safety. It may also allow the fuel to operate longer in the reactor to more fully utilize the uranium it contains.

LEU fuel conversion program

The U.S. Department of Energy (DOE) National Nuclear Security Administration (NNSA) Office of Material Minimization and Management (M3) Reactor Conversion Program has been working to convert research reactors globally from highly enriched uranium (HEU) fuel to low enriched uranium (LEU) fuel. Several U.S. high performance research reactors (USHPRRs), including the MITR, could not be converted using a previously qualified LEU fuel. A new type of LEU fuel based on a uranium and molybdenum (U-10Mo) alloy is being developed to allow the conversion of five USHPRRs. The conversion program activities include the qualification of the proposed fuel, U-10Mo alloy foil clad in an aluminum alloy, and the development of the fabrication techniques (Wilson et al., 2019). The primary changes due to the MITR LEU conversion are the fuel element design from 15-plate finned HEU fuel to 19-plate un-finned LEU fuel, reactor operating power increases from 6.0 to 7.0 MW, and a higher primary coolant flow rate from 125 to 150 kg/s (2000–2400 gpm). The new LEU “FYT” fuel element design consists of three types of fuel plates with different fuel meat thicknesses while maintaining the same fuel element outer geometry. MITR conversion study concluded that the proposed LEU fuel design with power increase will maintain sufficient safety margins during steady-state and transient conditions, fuel cycle lengths, and reactor performance to support its experimental program (Sun et al., 2018).

Fig. 4 is a diagram of the new MITR LEU fuel element design. It utilizes flat, plate-type, aluminum-clad fuel elements that are U-235 enriched to 19.75 wt%. Each fuel element consists of 19 fuel plates. The fuel plates are assembled between two grooved side plates which are 0.48 cm thick. The fuel plates are 0.12 cm thick, 5.86 cm wide, 58.42 cm long and are spaced 0.19 cm apart to form 18 cooling water passages. Within an element, the spacing between the fuel plates is maintained by the grooves in the side plates. End nozzles, which are designed to provide structural rigidity for the element, also maintain the necessary spacing between elements.

Each LEU fuel element will contain 968 g of U-235. The amount of U-235 is not evenly distributed among each fuel plate, where three different fuel core thicknesses are adopted. T-plates (Plate No. 1 and 19, yellow-color plates) have a fuel core thickness of 0.033 cm. Four Y-plates (Plate No. 2, 3, 17, and 18, orange-color plates) have 0.043 cm. Thirteen F-plates (Plates No. 4–16, red-color plates in Fig. 4B) have a fuel thickness of 0.064 cm. The fuel core is LEU enriched to 19.75 wt% U-235 in the form of a U-10Mo monolithic alloy. Like the HEU fuel, each plate has fuel 58.42 cm long and 5.29 cm wide. Plates remain clad with 6061 aluminum alloy (Al-6061) with 0.0025 cm zirconium interlayers between the fuel and cladding. The nominal thickness of the Al-6061 cladding with zirconium for T-plates, Y-plates, and F-plates are 0.043, 0.038, and 0.028 cm, respectively, so that the total thickness of each plate is identical (0.124 cm). Fig. 4 shows the LEU fuel element design. The comparison between the MITR HEU and LEU fuel is shown in Table 1. Table 2 is a summary of major operational parameters of HEU and LEU core.

The MITR LEU core startup plan is developed to follow the pre-operational testing, criticality studies, start-up experiments and stepwise power increase tests outlined in the MITR-II Startup Report after its major modifications (MITR Staff, 1977). Because of the

Introduction

The history of nuclear research reactors on the campus of North Carolina State University (NCSU) is extensive. In 1949, Dr. Clifford Beck (Professor and Head of the Physics Department) developed a proposal to establish the first university based educational nuclear reactor in the world (Beck, 1949). Partial funding for this reactor was obtained from the North Carolina based Burlington Mills Foundation and ground was broken on the current "Burlington" building in 1951. The total cost of establishing this reactor, and the associated laboratories, was \$630,000 US Dollars. On September 5, 1953 at 12.59 a.m., the Raleigh Research Reactor went critical and operated under the R-1 license as issued by the US Atomic Energy Commission (AEC). The R-1 reactor had a maximum power of 10 kWth. It operated with a homogenous core of uranyl sulfate that contains 836 g of uranium 235 (U-235) in the form of 1.39 kg of UO_2SO_4 (with an enrichment of 93.7% in U-235) diluted in 12.5 L of H_2O . R-1 operated for 2 years until June of 1955 when it was shut down and decommissioned due to corrosion issues with a total output of 60,000 kW-hours. Subsequently, three reactors were operated on the NCSU campus until the early 1970s. Fig. 1 shows pictures for establishing the R-1 reactor.

In 1969, NCSU initiated construction of the PULSTAR reactor based on a design that was demonstrated by American Machine and Foundry (MacPhee and Wett, 1963). The PULSTAR became operational with a maximum power of 1-MWth and achieved first criticality on September 9, 1972 at 1.52 a.m. This was a major facility that had all the elements of a modern education and research reactor including beam tubes for experimental facilities. In 1978, the Nuclear Reactor Program (NRP), where the PULSTAR reactor is housed, was formally established as a university center. The mission of the NRP derives directly from the institutional mission and focuses on the three pillars of education, research and discovery, and outreach and extension. Consequently, on annual basis the PULSTAR serves the educational and research essentials of hundreds of students (undergraduate and graduate) and faculty, supports the technological needs of various industrial and governmental organizations, and provides many public outreach opportunities for K-12 students and teachers, technical 2-year colleges, and the community at large. Since 2010/2011, the NRP carries the designation of "Board of Governors' Center" within the University of North Carolina (UNC) system. In this capacity, it continues to serve its mission objectives with focus on the 17 campuses of UNC.

The PULSTAR has been operational for 47 years and is currently undergoing a license extension review by the US Nuclear Regulatory Commission. As part of this review, the PULSTAR's power is to be upgraded to 2-MWth. Over the past 18 years, the PULSTAR initiated major upgrades of its operational capabilities and facilities (Hawari, 2017). This included enhancing core reflection, licensing of new fuel, and major digital upgrades of its control console and instrumentation. In addition, several facilities for non-destructive materials examination and fundamental science were established. This includes an intense positron beam facility, a neutron imaging facility, a neutron powder diffractometer, and an ultracold neutron source. Recently, a hot cell facility was installed. A fuel testing loop is expected to be operational by the end of 2019. Fig. 2 shows a picture of the PULSTAR reactor core, and its bay as it currently stands with its various facilities. Details of the reactor design and its facilities are presented in sections *PULSTAR reactor design* and *PULSTAR experimental and educational systems*.

PULSTAR reactor design

PULSTAR core design and characteristics

The PULSTAR is a light water moderated and cooled reactor. It is fueled with uranium dioxide (UO_2) fuel that has an enrichment of 4% and/or 6% in U-235 by mass. The fuel is configured as sintered pellets in zircaloy two cladding and arranged into pins with every

Fig. 1 The biological shield and bay of the R-1 reactor (left), the Burlington building (center), and Clifford Beck with the R-1 reactor core in 1952 (right).

Fig. 2 The PULSTAR reactor bay showing various facilities (left). The core of the PULSTAR reactor at 1-MWth full power (right).

pin containing 25 pellets. The pins are configured into assemblies with a square array of 25 pins per assembly. The core of the PULSTAR is configured of a square array of 25 assemblies. The core is reflected on two sides with beryllium reflector assemblies that are used to improve its neutron economy and enhance excess reactivity. **Fig. 3** below shows the details of the PULSTAR fuel and the current configuration of the core.

A typical PULSTAR core is loaded with 360 kg of U-238 and 13 kg of U-235. This results in a H_2O -to- UO_2 volume fraction of near unity, which results in a highly under moderated core. Consequently, the thermal neutron flux does not peak in the core but on the periphery, while the fast and epithermal neutron fluxes peak in the core. **Fig. 4** shows the results of an MCNP simulation illustrating the spatial distribution of thermal, epithermal, and fast neutrons in the PULSTAR core. Furthermore, due to the large loading of U-238, the PULSTAR has a significant component of fuel temperature feedback reaching $-0.03 \text{ mk}/^\circ\text{C}$ with an overall power defect reaching -3.3 mk . Originally, the PULSTAR was designed to allow pulsing of the reactor to a maximum power of nearly 2200 MW. However, the NCSU PULSTAR is no longer licensed to pulse its power. **Table 1** below gives fundamental parameters that characterize the PULSTAR core ([PULSTAR SAR, 2019](#)).

PULSTAR control and safety systems

Control of reactivity in the PULSTAR core is achieved using four control rods that are fitted with silver-indium-cadmium alloy (80%–15%–5%) absorber blades. Each absorber blade is 0.46 cm thick and 61 cm long. One of the rods serves as a regulating rod, while the other three rods serve as safety rods. The regulating rod may be positioned automatically based on a power setting entered into the Automatic Power Control System. Each control rod is connected to a drive mechanism by an electromagnet, which can be de-energized within 50 ms. The drive speed for the control rods is 32 mm/s and the maximum reactivity insertion rate is limited to 2 mk/s. **Fig. 3** shows a schematic of a control rod and its drive mechanism.

Fig. 3 The PULSTAR core and its layout (top). A schematic of the PULSTAR fuel (center). A schematic of the PULSTAR control rod and its drive mechanism (bottom, see section *PULSTAR Control and Safety Systems*). All dimensions are given in inches.

Fig. 4 The calculated energy and spatial distribution of neutrons in the PULSTAR core illustrating the significant flux of thermal neutrons (energy less than 0.5 eV) on the core's periphery (left). A picture showing the locations of the PULSTAR's in-pool rotating exposure ports (REPs), dry exposure ports (DEPs), and pneumatic transfer system (right). In addition, the PULSTAR's beam tubes are shown. By comparing the left and right images, the advantage of the resulting PULSTAR flux distribution can be observed.

Table 1 Parameters of the NCSU PULSTAR reactor that define its operational behavior. Unless indicated the values apply to both 1-MWth and 2-MWth operation.

Type of reactor	PULSTAR
Rated power (MWth)	1 (under upgrade to 2 MWth)
Type of fuel	Uranium dioxide (UO ₂)
Fuel enrichment (weight % U-235)	4% and/or 6%
Coolant/Moderator	Light water/light water (H ₂ O/H ₂ O)
H ₂ O-to-UO ₂ volume fraction	1.1
Core fuel loading (kg U-235)	13.3 (as of 2019)
Core inlet temperature (°C)	41
Average fuel temperature (°C)	145 (1-MWth), 223 (2-MWth)
Average coolant temperature (°C)	44
Fuel temperature coefficient of reactivity (mk/°C)	− 0.029 (1-MWth), − 0.028 (2-MWth)
Isothermal temperature coefficient of reactivity (mk/°C)	− 0.067
Moderator void coefficient (mk/cm ³) (reactivity feedback measured due to displacement of moderator)	− 0.01
Prompt neutron lifetime (μs)	80
Effective delayed neutron fraction, β _{eff} (mk)	7.33
Power defect (mk)	− 3.29 (1-MWth), − 5.60 (2-MWth)
Shutdown margin (mk)	35

PULSTAR cooling system

The PULSTAR reactor utilizes demineralized light water as coolant. The cooling system operates in forced convection mode, with downward flow through the core, and is designed to support the current power of 1 MWth and future operations at 2 MWth. In addition, at a power of 100 kWth or less, PULSTAR cooling can be supported using natural convection mode. The cooling system is comprised of primary and secondary subsystems. The primary subsystem has an open pool loop configuration and operates at atmospheric pressure. Water flows downward, at a rate of 32 L per second, through the core and transfers the heat generated by fission to the secondary subsystem using a plate type heat exchanger. Subsequently, the heat is removed by the secondary subsystem to the ultimate atmospheric heat sink using a standard counter-flow evaporative cooling tower. As a result, a pool inlet temperature below 41 °C is maintained with a temperature rise across the core of less than 7.5 °C. Fig. 5 below shows a rendering of the cooling system of the PULSTAR reactor and associated major components.

PULSTAR experimental and educational systems

In-pool irradiation capabilities

Facilities and locations for performing irradiations exist in the PULSTAR pool and in the vicinity of the core. This includes four vertical Rotating Exposure Ports (REP), which are typically used to perform neutron activation analysis (NAA), isotope production

Fig. 5 A schematic of the current PULSTAR reactor's primary and secondary cooling systems.

Table 2 PULSTAR reactor's in-pool facilities and available neutron flux levels.

Facility/capability	Description	Neutron flux
Rotating exposure ports (4 in-pool, ex-core)	6.4 cm ID wet sample irradiation terminus.	1.0×10^{13} thermal n/cm ² /s 1.0×10^{12} fast n/cm ² /s
Dry exposure ports (2 in-pool, ex-core)	3.2 cm ID dry sample irradiation terminus.	4.0×10^{12} thermal n/cm ² /s 1.0×10^{11} fast n/cm ² /s
Pneumatic terminus (1 in-pool, ex-core)	3.2 cm ID fast rabbit sample transfer system	1.0×10^{13} thermal n/cm ² /s 1.0×10^{12} fast n/cm ² /s
Pool standpipes (4 in-pool, ex-core)	8.9 cm ID dry sample irradiation positions	1.0×10^{11} thermal n/cm ² /s 5.0×10^9 fast n/cm ² /s

experiments, and materials exposure experiments (e.g., for radiation damage studies). Samples of interest are usually encapsulated, loaded into irradiation containers and rotated during irradiations to ensure exposure uniformity. In addition, the PULSTAR's pool contains Dry Exposure Ports (DEP) and standpipes that are typically used for instrument and detector exposure and testing. Another capability is the pneumatic transfer system, that allows for performing rapid irradiations of small samples, e.g., for performing NNA, and is used in industrial and medical applications. Fig. 4 above shows the location of the in-pool capabilities. Table 2 below gives typical neutron fluxes expected in these ports.

Beam tube instruments and facilities

Over the past 18 years, unique beam tube instruments and facilities have been established at the PULSTAR reactor. Fig. 6 below shows a layout of the PULSTAR bay floor. A fuel testing loop dedicated to fission product gas release measurements is located on beam tube #1 (Liu et al., 2018), a neutron powder diffractometer is located on beam tube #4 (DiJulio and Hawari, 2008), a neutron imaging facility is located on beam tube #5 (Mishra et al., 2005), an intense positron beam is located on beam tube #6 (Hawari et al., 2011; Liu et al., 2013), and an ultracold neutron source is located in the thermal column enclosure (Korobkina et al., 2014). Fig. 7 shows pictures of the intense positron beam and neutron powder diffraction instruments that are often used in pre and post irradiation examination of materials. Table 2 below lists the instruments and basic characteristics that are of importance to their performance and operations. In addition, the bay floor also contains auxiliary facilities such as the recently installed

Fig. 6 The PULSTAR bay floor showing the beam tube instruments and various facilities.

Fig. 7 Pictures of the Intense positron beam (left) and neutron powder diffraction (right) instruments at the PULSTAR reactor.

hot cell, which is used to support irradiation testing and isotope production, and a dark room that supports neutron radiography (Table 3).

Education and training capabilities

In addition to providing radiation experimental capabilities, the NRP with its PULSTAR reactor serves as a center for education in nuclear reactor and radiation physics. In this capacity, support is provided for typical reactor physics and engineering coursework in nuclear engineering. In addition, various training workshops are held annually to provide experience in reactor operations, radiation protection, and nondestructive examination to students at the K-12 and university levels.

Table 3 PULSTAR reactor instruments that are utilized in various testing and materials examination exercises.

Instrument/facility	Characteristics/performance
Fission gas measurement loop	Located on beam tube #1. Performs temperature dependent measurements of fission gas (krypton and xenon) release into flowing helium sweep gas using gamma-ray spectrometry.
Neutron powder diffractometer	Located on beam tube #4. Performs powder diffraction on samples with $\Delta d/d$ of 0.3%. The flux on sample is 10^5 n/cm ² ·s. Uses bent Si single crystal monochromator and beam energy of 30 meV (1.48 Angstroms). Able to extract diffraction patterns and pair distribution functions.
Neutron imaging facility	Located on beam tube #5. ASTM I ^A thermal neutron beam with flux on sample of 10^6 – 10^9 n/cm ² ·s. Spatial resolution in the range of 30–100 μ m depending on imaging modality. Capable of real time radiography and tomography.
Intense positron beam	Located on beam tube #6. Mono energetic positron beam generated using fission gamma-rays from the PULSTAR reactor's core in combination with capture gamma-rays in a cadmium shroud. Energy can be 1–17 keV and intensity reaches 10^9 e ⁺ /s. The beam is used in Doppler broadening and positron annihilation lifetime spectroscopy.
Ultracold neutron source	Located in the thermal column enclosure. Solid deuterium source (at 5 K) based on close coupling with fast neutrons leaking from the PULSTAR's core. Anticipated ultracold (300 nano eV) density of 30/cm ³ .

**Fig. 8** A remote IRL session (top). The main experimental interface displaying PULSTAR's control console telemetry such as power and control rod positions (bottom).

Fig. 9 The utilization of the PULSTAR reactor and associated laboratories represented as annual user hours covering education, service, and beam tube activities.

A unique modality that has been developed and offered at the PULSTAR reactor is the Internet Reactor Laboratory (IRL), which provides students at remote sites access to performing reactor physics and engineering experiments (e.g., control rod worth measurements, approach to critical analysis, etc.) (Hawari et al., 2020). Laboratory classes were first offered in 2004 within the United States. In 2010, and in collaboration with the US Department of State and the International Atomic Energy Agency (IAEA), classes were offered internationally. Recently, a second generation system (hardware and course modules) for remote education has been implemented. Fig. 8 shows pictures of an IRL session performed with the Jordan University of Science and Technology, and the main graphical interface representing the PULSTAR's control console.

Utilization and services

The Nuclear Reactor Program (NRP) is currently designated as a Board of Governors' Center within the University of North Carolina system of 17 campuses. In addition, it is available as a nuclear education and research center for users on a global scale. As indicated above, a development effort, that benefits from the characteristics and design of the reactor, took place over the past 18 years. This resulted in establishing various unique facilities and instruments and, in turn, drove unprecedented enhancement in the utilization levels of the NRP and the PULSTAR reactor. Specifically, utilization increased by nearly an order of magnitude for the period extending between the years 2000–19. Furthermore, the development of such capabilities allowed the NRP to become a partner in various US based national consortia including the US Department of Energy's Nuclear Science User Facilities (NSUF) and the US National Science Foundation's Research Triangle Nanotechnology Network (RTNN), and to participate in international efforts with organizations such as the International Atomic Energy Agency (IAEA) and the Nuclear Energy Agency (NEA) of the Organization of Economic Co-operation and Development (OECD).

Fig. 9 below shows the utilization data presented as annual user hours. As it can be seen in the figure, a major component of utilization is due to beam tube instruments. This is a direct indicator of the diversity of utilization as the beam tubes present users from various disciplines (engineering, science, etc.) with options to perform materials examination studies. Consequently, this clearly demonstrates that the utilization of a research reactor depends on expanding its availability to a multi- and inter-disciplinary user base.

Introduction

TRIGA[®] (Training, Research, Isotope, General Atomic) reactors were conceived and developed by the General Atomic division of General Dynamics Corporation. They had the objective of providing a training, research, and isotope production reactor with intrinsic safety features designed to significantly reduce the probability and consequences of a nuclear accident. This was termed a “walkaway safe” reactor.

General Atomics developed a unique fuel-moderator element consisting of a solid homogeneous alloy of uranium fuel and a zirconium hydride moderator (U-ZrH_n). These unique fuel elements provide the TRIGA[®] reactor with a large prompt negative temperature coefficient. Any increase in power immediately increases temperature in both the fuel and the moderator, instantly causing the fuel to become less effective (a decrease in reactivity). This decrease causes the reactor to return to safe power levels within milliseconds, much faster than an operator or electronic circuit could react.

This intrinsic self-regulating characteristic is integral to the TRIGA[®] reactor and permits safe, steady-state operation in addition to pulsing to very high power levels without the use of any mechanical or electronic control devices to return the reactor to a safe power level.

History

By 1956, the year General Atomics was formed, considerable progress had already been made in devising safety systems to minimize the possibility of reactor accidents. All nuclear reactors had some type of mechanical device to shut down the reactor if power levels exceeded a set limit. These systems usually employed circuits that would electronically analyze the level of radiation received by a detector. If the radiation level or its rate of increase exceeded preset limits, the safety circuits would initiate a reactor shutdown by dropping the control rods. However, out of a desire to make the reactor *inherently* safe, three prominent nuclear scientists, Freeman Dyson, Massoud Simnad and Edward Teller, set out to make the reactor fuel itself the primary means for ensuring safety (Dyson, 1979).

Rather than depend entirely on electronic circuitry or moving parts, General Atomics incorporated physical properties inherent to the fuel itself. These properties provide feedback which limits the reactor to safe power levels, or causes it to shut down. Initially proposed by Dyson, the “warm neutron principle” (which would later be named the Dyson Effect) described a way of creating an extreme negative temperature coefficient by coupling the moderator with the fuel itself.

In roughly 2 years of effort developing the methodology for the metallurgical development of this novel fuel design, a working prototype reactor called the TRIGA[®] Mark I (Fig. 1), was built. It was taken critical on May 3, 1958. The Mark I ran at a power level of 10 kW at the brand new General Atomic research park being developed in La Jolla, California (IAEA, 2016). Remarkably, this reactor operated until 1995.

This reactor design can arguably be said to have become renowned when General Atomics set up operating demonstrations of the Mark I reactor at the Second United Nations Conference on the Peaceful Uses of Atomic Energy in Geneva, Switzerland in 1958 and at the World Agricultural Conference in New Delhi, India in 1960. At this later conference, President Dwight Eisenhower famously pressed the button which began the operation of the reactor amongst the many dignitaries present at the event (Fouquet et al., 2003).

[☆] *Change History:* February 2021. Steve Reese updated explicit locations for the figures in revision 5 and removing Figure 7. Figure 8 in revision 5 is now Figure 7 in revision 6.

Fig. 1 The original TRIGA[®] Mark I reactor at the General Atomics research park in La Jolla, CA.

TRIGA[®] reactor basic design features

The heart of a TRIGA[®] reactor is its core. The core contains the fuel elements, graphite reflector elements, reflector assembly, and control rods. As a thermal reactor, the TRIGA[®] depends on thermal (low energy) neutrons to cause fission chain reactions in its fuel. Because the neutrons born in the fission of a ^{235}U atom are at a high energy, the probability of them causing another fission event before they leak out from the core is very low. A moderator is employed to thermalize (slow down) the fast (high-energy) neutrons. Moderation is the removal of energy from fast neutrons by collisions with light atoms of moderating material. In the TRIGA[®], neutron thermalization is achieved with zirconium hydride, water, and graphite as moderating materials; most of the moderation occurs in the fuel itself (General Atomics, 1958).

In any reactor, a certain percentage of the neutron population tends to “leak” out of the core: neutrons physically escape from the core and are absorbed elsewhere, such as in water or structural materials. To reduce this leakage, the core is surrounded by a graphite reflector, which reflects some of the escaping neutrons back into the core.

When a TRIGA[®] reactor is at power, the largest portion of energy being released by fission in the fuel appears as heat (Fig. 2). Water, moving by natural convection, is the primary reactor cooling mechanism except with the highest power designs (i.e., > 2 MW) where force flow is required. A secondary water system using a water-to-water heat exchanger removes heat from the primary coolant, and a forced air (or some other ultimate heat sink) cools the secondary water.

Normally a TRIGA[®] reactor is not operated for long periods of time at a high neutron flux. As such, many of the atoms born directly from fission that readily compete with the uranium in the fuel for neutrons are not present in high enough concentrations to tangibly affect the operation of the reactor. Some of these atoms have a large affinity to absorb neutrons (the physics term for this is called a cross section) that were intended to cause a fission reaction in the uranium fuel. Of these atoms, a radioisotope of xenon (^{135}Xe) has such a large cross section (i.e., affinity for absorption of neutrons) that it can prevent the startup of a reactor until it radioactively decays away. This phenomenon is referred to as “xenon preclusion”. If operation of the reactor does require long, sustained operations where xenon preclusion is potentially an issue, TRIGA reactors can simply add enough uranium fuel to overcome or override the ^{135}Xe that is created during the operation of the reactor.

Reactor fuel

The active part of each fuel-moderator element (Fig. 3), is approximately 3.05 cm in diameter and 38.1 cm long. TRIGA[®] fuel is a solid, homogeneous mixture of uranium-zirconium hydride alloy containing 8–30 wt% of uranium enriched up to 19.75% in ^{235}U . The hydrogen-to-zirconium atom ratio is approximately 1.6–1.0. To facilitate hydriding, the addition of super-saturated hydrogen in the fuel matrix, a 0.48 cm diameter hole is drilled through the center of the active fuel section; a zirconium rod is inserted into this hole after hydriding is complete (Simnad, 1980).

Each element is clad in 0.0508 cm of stainless steel, and all closures are made by heliarc welding. Two 8.9 cm sections of graphite are inserted into this stainless steel cladding, one above and one below the fuel, to serve as top and bottom reflectors for the core. Stainless steel end fixtures are attached to both ends of the can, making the overall length of the fuel-moderator element nominally 73.7 cm.

Fig. 2 The Oregon State TRIGA® Reactor operating at 1-MW.

Fig. 3 Illustration of a typical standard TRIGA® fuel element showing the orientation of the fuel slugs, molybdenum disks, and graphite inside the stainless steel cladding.

The lower end fixture supports the fuel-moderator element on the bottom grid plate. The upper end fixture consists of a knob for attachment of the fuel handling tool, and a triangular spacer, which permits cooling water to flow through the upper grid plate. The total weight of a fully loaded fuel element is only about 3.2 kg (7 lbs).

Instrumented fuel elements are also commonly used in TRIGA® reactors. An instrumented fuel element has three thermocouples embedded in the fuel (Fig. 4). The sensing tips of the fuel element thermocouples are located halfway between the outer radius and the centerline at the axial center of the fuel section, and 2.54 cm above and below the axial center. The thermocouple lead-out wires pass through a seal contained in a stainless steel tube welded to the upper end fixture. This tube projects about 7.62 cm above the upper end of the element, and is extended by two 3 m lengths of tubing connected by unions to provide a watertight conduit carrying the lead-out wires above the water surface in the reactor pool. In other respects, the instrumented fuel-moderator element is identical to the standard element.

Fig. 4 Illustration of a typical TRIGA® instrumented fuel element, used for measuring fuel temperature during irradiation, showing the path and location of the embedded thermal couples.

The specific characteristics that make TRIGA®-type fuels uniquely suited for use in extremely safe research-type reactors are covered in detail later in this article. A summary of the characteristics is given below:

- $\text{ZrH}_{1.6}$ is single phase up to 649 °C [delta phase region];
- low hydrogen equilibrium disassociation pressure at normal fuel temperatures;
- high hydrogen retention;
- high heat capacity;
- low thermal expansion coefficient;
- relatively low chemical reactivity with water;
- high fission product retention;
- very large negative prompt temperature coefficient of reactivity;
- high burnup possible by addition of burnable poison; and
- high loading of uranium possible with insignificant change in fuel material properties.

Pulsing capability

With the development of the inherently safe fuel itself, a remarkable ability to operate reactors utilizing this fuel in a prompt critical condition was created. This ability comes from the heart of the mechanism that creates the intrinsic safety of the fuel.

When a reactivity insertion exceeds the fraction of delayed neutrons, the fission chain reaction is supported by prompt neutrons. Because the mean time between generations of prompt neutrons born from fission is so short, it is impossible to mechanically control the rate of increase of this reaction.

Several mechanisms within the uranium-zirconium hydride fuel matrix allow for the safe, controllable rapid insertion of a large amount of negative reactivity. The molecular structure of the fuel matrix and the presence of the burnable poison erbium both contribute to a large prompt negative fuel temperature coefficient of reactivity. The ^{167}Er absorption cross section has a strong, broad, resonance that peaks at 0.5 eV. As the fuel temperature increases after a large positive reactivity insertion, the spectrum of thermal neutrons in the core is shifted to higher energies caused by scattering collisions with the hydrogen in the fuel matrix. This spectral shift pushes more neutrons into the resonance absorption peak of the erbium, increasing the probability of neutron capture in the erbium prior to fission. This strong, negative fuel temperature feedback ($\sim 10^{-4} \Delta k/k/^{\circ}\text{C}$) allows for the TRIGA® to be safely pulsed to a power thousands of times larger than that of steady-state operation (Simnad et al., 1976). Pulses as high as \$5.50, obtaining peak powers on the order of 6400 MW were demonstrated at the General Atomics Mark F reactor.

It is not clear when the first pulse of a TRIGA® reactor happened but it is likely it occurred in late 1958 with the original Mark I reactor at General Atomics. That reactor was famously first publically pulsed by Nobel Laureate Niels Bohr by the simple push of a button at the inauguration of the new General Atomics research facilities in Ja Jolla in 1959. By the time that reactor was decommissioned, it had performed over 13,000 pulses (IAEA, 2016).

TRIGA® fuel development

The development and use of U-ZrH fuels for the TRIGA® reactor began at GA in 1957 and continues today. Over 6000 fuel elements of seven distinct types have been fabricated for the more than 60 TRIGA® research reactors operated in various countries around the world. The earliest of these has now passed 50 years of operation. U-ZrH fuel has exhibited unique safety features including a large negative prompt temperature coefficient of reactivity, high fission product retention, chemical stability when quenched from high temperatures in water, and dimensional stability over large swings of temperature.

TRIGA® fuel was developed around the concept of inherent safety. A core composition was sought which had a large negative prompt temperature coefficient of reactivity such that if all the available excess reactivity were suddenly inserted into the core, the resulting fuel temperature increase would automatically cause the power excursion to terminate before any core damage resulted. Experiments performed in the late 1950s demonstrated that zirconium hydride possessed the basic mechanism needed to produce this desired characteristic. Additional advantages include ZrH's high heat capacity, allowing construction of a reactor with a relatively small core size and high flux values due to the high hydrogen content of the fuel rods, and can be used effectively to fabricate rugged fuel rods.

The standard TRIGA® fuel contains 8.5 wt% uranium (20% enriched) as a fine metallic dispersion in a zirconium hydride matrix. The hydrogen to zirconium (H/Zr) ratio is nominally 1.6 (in the face-centered cubic delta phase). The equilibrium hydrogen dissociation pressure is governed by the composition and temperature. For U-ZrH_{1.6}, the equilibrium hydrogen pressure is 1 atm at about 760 °C. The single-phase, high-hydride composition eliminates the problems of density changes associated with phase changes and with thermal diffusion of the hydrogen. A highly-enriched version of TRIGA® fuel titled "Fuel Lifetime Improvement Program" or "FLIP" (with a 70% enrichment) contained up to about 3% erbium as a burnable poison in order to increase the core lifetime and also contribute to the large negative prompt temperature coefficient (Simnad, 1980). The calculated core lifetime for FLIP fuel in a typical TRIGA® reactor was approximately 9 MW-years. However, FLIP fuel is no longer available because the enrichment exceeds 20%, the accepted maximum enrichment of low-enriched uranium (LEU) fuel.

In early 1976, GA undertook the development of fuels containing up to 45 wt% uranium (3.7 g U/cc) in order to allow the use of LEU fuel to replace the highly-enriched fuels while maintaining long core life. The 45 wt% fuel contains 19.75% uranium (referred to as 20-wt% although the actual number is just under 20-wt%). These fuels were fabricated successfully, with the required hydrogen content and erbium loading. The structural features of the hydrated LEU fuel were similar to those of the well-proven 8.5- and 12-Uwt% fuels, as shown by metallographic, electron microprobe analysis, and X-ray diffraction examination (Simnad, 1980). Detailed evaluations of the new LEU fuel have shown that it performs essentially identically to the older standard TRIGA[®] fuel.

Nuclear design and analytical studies have shown that the prompt temperature coefficient for the 20-wt% uranium fuel is essentially the same as that for standard fuel over the temperature range of interest (20–700 °C). The prompt temperature coefficient for the more highly uranium-loaded LEU fuel shows a temperature dependence (i.e., increasing with temperature), whereas the coefficient is relatively constant for standard fuel. The value of the prompt temperature coefficient of reactivity is slightly lower for the 30-wt% uranium fuel compared to the highly-enriched fuel it replaces; however, it is still large and significantly higher than the prompt temperature coefficients for any other type of reactor fuel.

Inclusion of erbium burnable poison in the TRIGA[®] LEU fuel has enabled core lifetimes of up to 3000 MW-d to be predicted for the 30-wt% fuel; this is the core life from the time of initial refueling to end of useful life. There are various TRIGA[®] fuel forms available today with a variety of enrichments and weight percents (Table 1). Although some early versions of 8.5/20 and 20/20 fuels had aluminum cladding, all fuels available today have Type 304 stainless steel cladding or Incoloy-800 for the 45/20 fuels. The most common TRIGA fuel types made today are the 30/20 and the 20/20 TRIGA fuels.

TRIGA[®] fuel is characterized by inherent safety, high fission product retention, and the demonstrated ability to withstand water quenching with no adverse reaction from temperatures to 1150 °C (Foushee and Peter, 1971). After this temperature, hydrogen migration can lead to plastic deformation of the cladding. The basic limit for TRIGA[®] fuel was therefore determined by this dissociation of hydrogen from the U-ZrH_n fuel. A fuel temperature safety limit of 1150 °C for pulsing precludes loss of cladding integrity when the cladding temperature is below 500 °C. When the cladding temperature equals the fuel temperature, the fuel temperature limit is 950 °C.

Reactor versions

Beginning with the original Mark I reactor at the General Atomics site in La Jolla, General Atomics went on to design six unique versions of the TRIGA[®] reactor. Fundamentally, the defining common characteristic of each was the use of the U-ZrH_n fuels. All are open pool-type reactors that, except for the highest power design, have very similar core lattice configurations. The differences between the designs are the irradiation facilities and capabilities.

The original Mark I was a below-ground version of the open pool TRIGA[®] reactor with a circular grid and annular reflector. The reactor core is a cylinder consisting of cylindrical rod-type fuel-moderator elements and graphite reflector elements organized in rings. Water occupies approximately one-third of the core volume. An annular radial reflector surrounds the core and is supported by an aluminum platform at the bottom of the tank. The reflector consists of graphite with a 5.08 cm layer of lead on the periphery to reduce the gamma dose emanating from the core. A typical Mark I core utilizes approximately 90 elements in a circular grid array. The number of elements varies depending on the power level, burnup, and grid lattice but generally range from 85–120 elements for all versions of TRIGA[®] reactors. With this design reactor powers can reach as high as 2 MW, but typically are 250 kW to 1 MW. All are cooled by natural convection. The reactor is controlled by three or four neutron-absorbing control rods, classically called the shim, safety, regulating, and for reactors capable of pulsing, a transient control rod. The shim, safety and regulating rods are equipped with a fueled follower while the transient rod has an air follower. Typically three or four neutron detectors monitor the neutron flux, which is then used to indicate reactor power level. An automatic control system is incorporated to maintain the reactor at desired power levels by automatically adjusting the regulating rod height.

One of the main purposes of this reactor is to perform neutron irradiation of various materials. Irradiation facilities of a typical Mark I consist of a 40-position rotating specimen rack, a pneumatic transfer system, three in-core irradiation tubes, and a central thimble. The rotating specimen rack, also known as the “Lazy Susan,” is in a watertight assembly located in a well in the top of

Table 1 Nominal characteristics of TRIGA[®] fuels (NUREG-1282, General Atomics Technologies, 1987).

Fuel type (U wt%/enrichment%)	LEU 8.5/20	LEU 12/20	LEU 20/20	LEU 30/20	LEU 45/20	HEU FLIP
Uranium content (mass %)	8.5	12	20	30	45	20
²³⁵ U enrichment (mass % U)	19.75	19.75	19.75	19.75	19.75	70
Erbium content (mass %)	0	0	0.5	0.9	1.8	1.6
Original ²³⁵ U Mass (g)	39	55	99	162	282	137
Core lifetime (MW-d)	100	145	1200	3000	4000	3500
Uranium volume (%)	2.6	4.7	6.8	11.2	19.5	2.6

the reflector. The pneumatic transfer tube terminates into one of the lattice positions of the core. Dry, vertical in-core tubes are also commonly incorporated. A center location, usually called the central thimble, penetrates the center of the core, along its vertical axis; this location produces the highest thermal neutron flux.

The Mark II design (Figs. 5 and 6), is essentially an above-ground version of the Mark I, able to utilize the same core configurations and geometries as its predecessor. A large semi-octagon shaped concrete bioshield provides shielding in the horizontal plane, and contains a cylindrical reactor tank nominally 2 m in diameter by 8 m in depth. The above ground configuration allows for a substantial number of additional irradiation capabilities, most notably beam ports. A typical Mark II has four beam ports projecting from the reactor core through to the outside of the bioshield. Three of the beam ports are oriented radially out from the core; the fourth is tangential to the core to promote a beam with a high thermal neutron content while minimizing epithermal and fast neutrons as well as photons. This configuration is ideally suited for thermal neutron radiography. Mark II designs also typically have a thermal column, a large square compartment filled with graphite that produces a neutron field with a very high cadmium ratio (i.e., thermal to fast neutron ratio). It allows for samples to be inserted in the middle through the use of a large and heavy (~9 tons) wheeled door. Reactor power typically found in a Mark II design range from 500 kW to 2 MW, and utilize natural convection cooling. Thermal neutron fluxes of greater than $1\text{E}13 \text{ n cm}^{-2} \text{ s}^{-1}$ are easily achievable for a 1 MW TRIGA® reactor.

An early prototype design, designated the Mark F, was built at the General Atomics facility in 1960 and served as a testbed for the fuel development program. Nearly identical to the Mark F was the Mark III design. The Mark III, is a modified version of the Mark II which incorporates a number of novel features not found in other TRIGA® reactors. While the core lattice arrangement is similar to Mark I and Mark II designs, the most notable unique characteristic of the Mark III is the core attached to a moveable bridge gantry. This allows for the core to be moved in close proximity to beam facilities, some of which are similar to the Mark II while others are unique to the Mark III design. One such unique facility is an exposure room designed to accommodate large experimental setups. This design is also associated with a large elongated pool, with nominal dimensions of $7.6 \text{ m} \times 3.0 \text{ m} \times 7.6 \text{ m}$. These reactors were designed for steady-state power levels from 1–2 MW under natural circulation conditions.

The Annular Core Pulsed Reactor design was created to take full advantage of the unique pulsing capability of TRIGA® fuel. Typically, the U-ZrH_n lattice is arranged in a hexagonal grid with a large dry central irradiation cavity. These cores were designed to operate at modest steady-state power levels of 500 kW but produce pulses on the order of 22,000 MW (Dee et al., 1966). The fuel is unique in that the outside cladding of the fuel elements used on TRIGA®-fueled annular core reactors are dimpled to allow for the higher peak fuel temperatures observed on the large pulses.

The Multipurpose Reactor design was created to enable reactor powers much higher than previous designs. Natural convection cooling of standard TRIGA® fuel is limited to no more than approximately 2.5 MW. Above this, forced cooling is required. Force cooling for these higher-powered reactors takes the form of a simple reverse flow configuration (water is forced down through the core lattice from the top) at moderate flow rates. Additionally, the TRIGA® fuel form is changed considerably to handle the higher

Fig. 5 Vertical cutaway illustration of a typical Mark II TRIGA® reactor. The orientation of the core at the bottom of a cylindrical tank surrounded by the concrete bioshield with the embedded irradiation facilities can be seen.

heat flux off the surface of the fuel. In these reactors, the same U-ZrH_n is utilized but with two important differences. First, the fuel is much thinner, created in the form of 13 mm diameter fuel pins placed in a tightly packed square pitch configuration. Second, the weight percent of the fuel is much higher at 45%. Although this design is intended to operate from 5 to 20 MW, pulsing is not allowed in reactors operating above 3 MW. As of 2019, the only Multipurpose Reactor built is at the Institute of Nuclear Research in Pitesti, Romania.

The final design are the converted reactors. This is a group of reactors that were originally fueled with plate-type uranium-dispersion fuels (sometimes referred to as material test reactors or MTR) and subsequently converted to TRIGA[®] reactors by replacing the plate-type fuel with U-ZrH_n fuel (Fig. 7). Usually, the square pitch core lattice structure was retained. To fit the existing MTR core dimensions and orientation, General Atomic designed TRIGA[®] fuel with a slightly smaller diameter which could then be arranged in a square cluster assembly composed of four of these thinner TRIGA[®] fuel elements. Once converted, their physics and operational characteristics are nearly identical to original TRIGA[®] reactor designs. In all, 13 reactors were converted in this manner.

TRIGA[®] reactor utilization

TRIGA[®] reactors provide an optimum blend of capabilities ideally suited for a research or academic environment. As a result, 69 TRIGA[®] reactors have been built or converted to TRIGA[®] fuel in more than 30 countries, making it the most widely produced reactor of any kind. First and foremost this proliferation was driven by the inherent safety features offered by the fuel design: this is perhaps the most significant consideration for siting these reactors which are commonly found in urban environments or on university campuses. Even in the worst credible accident the resulting dose to the general public would be on the order of 1 mSv for a 2 MW TRIGA[®] fueled reactor due to the excellent fission product retention and high melting point.

In an academic setting, research reactors at universities have to balance the competing needs of research, academia, and service. Which need dominates is largely dependent on reactor power. Lower power reactors tend to place more weight on the academic rather than the research mission, with service work being a distant third. Successful research reactors of medium power usually place more weight on research, followed by the academic uses and with service work being the least important. Medium power research reactor programs tend lean towards the academic mission. Research reactors of higher power typically emphasize the research and service work more than an academic mission. The main reason for this is the notably higher operational tempo at high power research reactors. The increased neutron flux is best utilized for research or service, such as isotope production, only achievable in substantial quantities through continuous full power operations (IAEA, 2014).

Summary

TRIGA reactors are the most widely produced of any research reactor in the world, owing largely to the incredible versatility of the reactor design. From small 100 kW educational focused reactors to 14 MW research oriented designs, TRIGA reactors have proven to be immensely valuable instruments of science and engineering at universities and research centers. Furthermore, TRIGA[®] reactors

Fig. 7 Overhead view of the TRIGA® reactor at Washington State University. Called a conversion TRIGA®, this is an example of a reactor that was originally designed to utilize plate fuel but whose fuel was later replaced with TRIGA® fuel.

also provide ideal in terms of safety. The inherent safety of TRIGA® reactors has been demonstrated by the extensive experience acquired from similar TRIGA® systems throughout the world. This safety arises from the extremely large negative prompt temperature coefficient that is characteristic of uranium-zirconium hydride fuel-moderator elements used in TRIGA® systems. As the fuel temperature increases, this coefficient immediately compensates for reactivity insertions. This results in a mechanism whereby reactor power excursions are terminated quickly and safely.

Introduction

Energy in the world

One of the major challenges that our society faces is the increasing demand for energy in general and electricity in particular. According to international references (DOE/EIA, 2019; OECD, 2016) global energy requirements will increase by 50% by 2035. Many factors play a role in this like the expected growth of world population, making electricity available to the population that currently has not yet access to electricity, the higher consumption in developing countries and the average life expectancy increase, to name a few.

During the last century, our energy supply was mainly based on fossil fuels. While the increase of the global energy requirement is in a continuing trend, the available sources of energy are also being increasingly tapped. Fossil fuels are still in sufficient supply, are easily accessible and at a reasonable price. However, we are confronted today with excessive CO₂ emissions, so the use of fossil fuels needs to be limited. At the same time, renewable energy sources such as solar and wind based electricity generators cannot fully satisfy the global demand. Therefore, different countries recognize that nuclear energy needs to be included in the “energy basket” of the future.

Nuclear energy

Nowadays thermal nuclear reactors use nuclear fission of the fissile isotope of uranium (²³⁵U, and in a smaller amount, plutonium) induced by thermal (slow) neutrons to generate heat and electricity. During this process, the fissile atom is split. The current nuclear work horse for electricity production, the light water reactors, only fission a small portion (<1%) of the raw uranium. When nothing changes from a technological point of view, the known uranium resources may become scarce around the end of the century (OECD/IAEA, 2018) although there are scientists who believe that uranium is practically renewable (Conca, 2021; Herring, 2021). Reactors in which the neutrons have higher energies (so-called fast reactors) can utilize close to 100% of the natural uranium and hence need a smaller amount of uranium ore per unit of energy generated. Moreover, the fast reactors can also utilize depleted uranium huge quantities of which had been accumulated as “waste” in the uranium enrichment plants. These reactors would allow more efficient use of the uranium resources.

During their operation present nuclear power reactors produce high-level radioactive waste (HLW). For this high-level radioactive waste, a technical and socially acceptable solution is necessary. Even though the solutions that are being considered at this moment, like geological disposal, might offer a technically viable solution, the time scale needed for the radiotoxicity of the waste to drop to the level of natural uranium remains very long, which is not acceptable for part of the public.

In a nuclear reactor the released neutrons from a fission reaction can undergo various reactions; they can induce a new fission leading to the birth of new neutrons, they can be absorbed in the structures of the reactor or even in the fuel without inducing fission leading to the production of heavier elements than uranium (like neptunium (Np), plutonium (Pu), americium (Am), curium (Cm), etc.) or they can leak out of the reactor core and lost to the chain reaction. To maintain the chain reaction one needs a critical mass and critical dimensions of the reactor and these correspond to quantities of fissile materials arranged in a given geometry in such a way that the amount of neutrons produced by fissions is balanced by the amount of neutrons lost either by sterile absorptions or by leaking out of the reactor core. When these conditions are met, and the chain reaction is sustained by the system itself, the reactor is “critical.”

The core in an Accelerator Driven System (ADS) will be subcritical; it will not be able to establish a self-sustained chain reaction. In this context the term subcritical means that, on average, for each generation of fission neutrons, less than one neutron will be able of initiating a subsequent nuclear fission. This situation can be achieved by limiting the amount of fissile material in the core, in this way the chain reaction is not self-sustaining. One can operate such a reactor in continuous mode (i.e. constant power), by supplementing the fission neutrons by neutrons from an external source. In an ADS, these supplementary neutrons are produced by spallation reactions (Fig. 1), during which high-energy protons, coming from a particle accelerator, are impinging on a spallation target made of a heavy metal like lead. In the course of the spallation process, the liquid metal nuclei emit a large number of neutrons whose energy spectrum is made of two parts: a conventional fission spectrum and a high-energy tail up to the energy of the incident proton. At 600 MeV, each impinging proton on a lead target would produce about 10 spallation neutrons.

As already mentioned, the generation of nuclear energy from uranium produces, besides energy, also high-level nuclear waste. The HLW quantity one speaks about depends of the considered fuel cycle. To illustrate this let us consider the various fractions

Fig. 1 Spallation vs. fission.

produced by using one ton of uranium as fuel in a Pressurized Water Reactor (PWR) after four and a half years (corresponding to an average burn up of 50.000 MWd tHM⁻¹):

- 935 kg of uranium;
- 12 kg of plutonium;
- 2.4 kg of Minor Actinides (MA), divided into
 - 1 kg of neptunium;
 - 0.8 kg of americium and
 - 0.6 kg of curium;
- 50 kg of fission products (FP), from which a small part (3.5 kg) is long-lived (and called long-lived fission products or LLFPs).

Partitioning and transmutation

Partitioning is the term used for the chemical processes needed to separate the different elements present in spent nuclear fuel (actinides like uranium and plutonium; minor actinides like neptunium, americium and curium; fission products like cesium and strontium) such that a dedicated treatment can be applied to each stream (Bart, 2021). This is analogous to the concept of recycling in household waste: we separate paper from glass; compostable from plastic, etc.

Transmutation is the process where we subject the minor actinides and/or plutonium, to a flux of fast, high energetic neutrons. Why? Because the fission-to-capture ratio of fast neutrons is significantly larger than for thermal neutron. That is, a fast neutron has a higher probability to induce a fission of the actinides, and hence transmute them into fission products, than the probability that it would be captured by the actinide nucleus and convert it to a nucleus of an even heavier element (what is more likely to happen with slow, thermal neutrons).

Fig. 2 below illustrates the capture and fission cross-sections of ²⁴¹Am as function of energy. We can see clearly that below 1 MeV the capture cross-section is 2–3 orders of magnitude higher than the fission cross-section. The latter becomes predominant beyond a high-energy threshold a little bit below 1 MeV. Thus it is obvious when considering MA's transmutation one needs to conduct it in fast neutron spectrum reactors. This is the first condition for a successful transmutation of MA's. Hence, transmutation requires systems that run on fast neutrons. Plutonium is currently being recycled in LWRs in a few countries, like France (Boullis, 2021; Marin, 2021).

These fast neutron systems cannot be cooled by water since this would slow down the neutrons too much. Therefore, typical coolants for these fast neutron systems are liquid metals like sodium or lead/lead-bismuth.

Fig. 2 Neutron spectrum of ²⁴¹Am. Figure is produced using JANIS 3 (Java-based Nuclear Information Software: <http://www.oecd-nea.org/janis>).

Another issue that one has to consider when dealing with transmutation of minor actinides like neptunium, americium and curium in a critical fast neutron reactor is guaranteeing the reactivity safety control of the reactor. The reactivity control being driven by the weighted average value of the effective delayed neutron fraction of the reactor core $\langle \beta_{\text{eff}} \rangle$ and due to the fact that minor actinides are having smaller values of delayed neutrons compared to uranium isotopes (see [Table 1](#)).

The doubling time of the neutron population (and fission power) in the reactor or the period of the reactor being proportional to this delayed neutron fraction:

$$T = \frac{1}{\rho} \left[\frac{\ell}{K_{\text{eff}}} + \sum_{i=1}^M \frac{\beta_i}{\lambda_i} \right]$$

It is obvious that the minor actinides will have a negative effect on the time constants of the system. The higher the amount of minor actinides in the core inventory is, the faster kinetically the reactor becomes. Therefore, with the knowledge and technology of today, we consider only a loading of 2% to maximum 5% of minor actinides inventory in a critical sodium fast reactor core.

This would mean that, in order to transmute the legacy waste of more than 40 years of PWR/BWR operation, numerous fast reactors have to be deployed. In a country that wants to continue with nuclear energy, this transition to a fast reactor fleet is credible (since these reactors have other advantages like less uranium resource use). But in countries that have decided to phase-out nuclear power, the option of building a fast reactor fleet is not acceptable.

For those countries in phase out, accelerator driven systems provide a solution. Since in these systems the time constants are driven by the accelerator and not by a self-sustained chain reaction, they can be loaded with much more minor actinides: up to 40% of the core contents and the remaining 60% core inventory can be made of Pu that should be also dealt with of a MOX made of the Pu and depleted U. Studies ([Van den Eynde et al., 2013](#)) have shown that for all European countries in phase out, seven 400 MWth ADS units would be required to transmute all minor actinides in a time frame of about 100 years.

Partitioning and transmutation (P&T) has three main goals:

- A reduction of the radiological hazard associated with spent fuel by reducing the inventory of minor actinides and plutonium;
- A reduction of the time interval required to reach the radiotoxicity of natural uranium;
- A reduction of the heat load of the HLW packages to be stored in the geological disposal leading to its efficient use.

P&T will not replace geological disposal but it is a means to ease the engineering of such a disposal and to reduce the life-time of the disposal site to times that are maybe apprehensible by humans.

The time scale needed for the radiotoxicity of the waste to drop to the level of natural uranium will be reduced ([Fig. 3](#)) from a “geological” value (500,000 to 1 million years) to a value that is comparable to that of human activities (several hundreds of years) ([OECD/NEA, 2002, 2006](#)).

In Europe, research and development has been built on the so-called four building blocks:

1. Advanced partitioning of PWR/BWR fuel. This is known technology, much of it already at semi-industrial scale.
2. Fabrication of minor actinide loaded fuel.
3. Transmutation in dedicated industrial transmutation facilities
4. Reprocessing of the transmuted fuel.

MYRRHA, Multipurpose hYbrid Research Reactor for High-tech Application ([Aït Abderrahim et al., 2010](#), described further on in this chapter), aims to be a prototype for the conceptual industrial transmuter, EFIT (European Facility for Industrial Transmutation), designed in the IP-EUROTRANS project ([Mansani et al., 2012](#)).

Fig. 4 Concept of an accelerator driven system.

ADS technology

The concept of ADS combines a particle accelerator, a spallation target and a nuclear reactor with a subcritical core (see Fig. 4). In most proposals, a proton accelerator can be found. The protons are injected by the accelerator onto a spallation target, where they produce neutrons for driving the subcritical core. Except for the subcritical state, the core of an ADS is very similar to that of a critical reactor. The different components of an ADS are discussed in detail in the following sections.

Accelerator

The accelerator is the driver of the ADS. The accelerator provides the high-energy protons that are used in the spallation target to create neutrons, which practically “drive” the subcritical core. The accelerator can be either a linear accelerator (LINAC) or a circular accelerator (cyclotron). The accelerators used in an ADS must be high-power accelerators and must have an extremely high reliability and availability. These accelerators are under continuous development and the construction of these machines seems feasible (see also Garcia, 2021).

Particle accelerators delivering a beam on a target can be organized according to the time structure of their beam:

- Direct Current (DC) beam delivery: this beam with no time structure is typically obtained from a DC accelerator;
- Continuous Wave (CW) beam delivery: in order to be accelerated by radiofrequency (RF) fields, the beam has to be subdivided in small packets called bunches and the RF has to be synchronized with the bunch progression through the accelerator. If the resulting bunch train is delivered continuously to the target, the beam delivery is called continuous wave. For providing such a beam, the accelerator must operate in a steady state characterized by constant guiding fields and constant RF frequency;

- Pulsed beam delivery: if the bunch train is interrupted in a periodic way (but with a frequency that is much smaller than the RF frequency) a beam on/off cycle is obtained, leading to pulsed operation. Within the pulse, the bunch structure of the beam remains present.

The choice between a LINAC and a cyclotron depends on many factors. In both cases, it is important to specify the beam characteristics, and more specifically to minimize the amount of beam interrupts. For most ADS the accelerator delivers the particles in continuous mode, although pulsed operation could be used as well (e.g. for testing purposes).

Linear accelerators have the possibility to place the transverse focusing elements (quadrupoles) at frequent intervals along a LINAC, as well as longitudinal focusing, which set a higher limit to the charge per bunch that can be accelerated without significant beam losses. This results in the fact that a LINAC could accelerate a current one to two orders of magnitude higher than a cyclotron, without having problems of beam extraction. The major drawback of a LINAC is its length, which depends on the final beam energy and accelerating gradient. This length of the LINAC is an important factor in the cost of the facility, as most of the accelerator needs to be shielded against radiations.

The base of a cyclotron is the so called “cyclotron resonance”: in a magnetic field, constant in time and perpendicular to the beam orbit, the particle revolution frequency is fixed and independent of the particle energy. The major drawbacks with cyclotrons are the absence of good focusing and the beam extraction. The deflecting system, which guides the beam out of the accelerator, is only permitted to touch a negligible fraction of the beam. The current limit of the cyclotron is given by a design requirement to produce a clean beam at the outer radius of the machine. The maximum proton energy that can be reached by cyclotrons is 1 GeV.

The accelerator must have a high reliability and efficiency. Indeed any beam trip occurring will lead to a reactor shut-down equivalent to an unforeseen SCRAM. As after a SCRAM the operational procedure of the restart of the reactor would require hours if not days this will be very penalizing the ADS operation in terms of availability. Therefore, the proposed operation approach would be to ignore very short beam trips with duration below 3 s (in the case of MYRRHA) as the thermal inertia of the lead-bismuth coolant will be protecting the reactor and the spallation target guide tube from temperature mechanical stress transients. When the accelerator cannot be restarted within 3 s leading to thermal stresses than one has to apply a “SCRAM” restart procedure with progressive ramping up of the current hence the power of the reactor. As such within MYRRHA we are limiting the number of beam trips longer than 3 s to 10 of them for an operating cycle of the reactor of 3 months.

Spallation target

The spallation target is a neutron source providing primary neutrons that are multiplied by the surrounding subcritical core. The primary neutrons are produced by the spallation reaction of heavy-metal target nuclei, bombarded by the high-energy particles generated by the accelerator.

The spallation target is one of the most stressed components of an ADS. The spallation target is designed to generate the maximum amount of neutrons while it must be able to safely evacuate the heat generated by the spallation process. In addition, the mixed proton-neutron irradiation field that typically can be found in the spallation target of an ADS imposes very specific conditions in the design and operability of the target and effects all thermo-mechanical characteristics for these targets. The target of an ADS must be cooled, mostly by gas, heavy water or liquid metal.

There are two options for the spallation target: a solid target or a liquid metal one. Within the operational, lower-power facilities there is a lot of experience with solid targets, especially when combined with an accelerator which delivers a pulsed beam. These solid targets are difficult to cool and suffer from radiation damage. The target should be cooled even after the accelerator is shut off. The path for solid targets for use in an ADS is abandoned in favor for the liquid metal targets.

For higher-power facilities ADS, the use of a liquid metal spallation target is preferred. Both lead as lead-bismuth eutectic (LBE) are primary candidate liquid metals for spallation targets in an ADS. The cooling of a liquid metal spallation target is inherent to the design of the system; there is a constant flow of liquid metal coolant. At the same time, it is possible to achieve higher power densities without having significant irradiation damage to the target. The drawback of a liquid metal target is that the coolant, and especially lead or LBE, can cause erosion or corrosion to the structural materials that are in contact with the coolant.

Design difficulties of liquid metal spallation targets include the following: First, we have the choice of structural materials for the target. The materials must withstand the thermo-mechanical loads on the targets and must be compatible with the liquid metal. Secondly, a reliable interface between the target and the beam guide tube must be designed. This may take the form of a solid beam window or a windowless design. A beam window is exposed to a significant flux of high-energy protons and neutrons at high temperatures and to a very corrosive environment. Therefore, it is very likely that the beam window will have to be replaced periodically because of material damage. The use of a windowless target will alleviate the window embrittlement issue. Nevertheless, when the proton beam will interact with the heavy liquid metal serving as the spallation target material, volatile spallation products will be produced. The later can escape out of the reactor via the proton beam guide line and will be inducing the contamination of the accelerator. Therefore, in a windowless target design a so called “cold window” should be introduced in the last meters of the proton beam line far away from the place where spallation reactions are occurring. As such this “cold window” protecting the accelerator from contamination will be submitted only to proton irradiation and will result in approximately 1.5–2 times lower radiation dose less harmful in comparison with the window target design.

Subcritical core

The subcritical core of an ADS is constructed in such a way that it does not have enough fissile material to reach criticality. Non self-sustaining fission chain reaction is established by the spallation neutrons. The subcritical core of an ADS acts as an amplifier: on average ~ 15 neutrons are produced for each proton.

The energy spectrum of the subcritical core depends on the application of the core. For the transmutation of minor actinides, a fast neutron spectrum has various advantages among them a larger excess of neutrons, a reduced amount of minor actinide production in the core and more fission energy generation per spallation neutron.

The evolution of core composition with time (i.e., with burnup) and temperature feedback effects will have an effect on the multiplication factor of the core, as in critical systems. However, for a subcritical core, the behavior is dominated by the external source and its variation in time. The closer to a critical system, the feedback elements of the core will become more important. There are no final criteria to define an optimal level of subcriticality.

In critical cores, reactivity of the core and the power level of the reactor are adjusted using control rods. With an ADS, it should be possible to control the power level of the subcritical reactor through the external source. When a core is working in “source dominated” mode, the shutdown of the source has an instantaneous effect to reduce power. The inverse effect, a sudden increase of the source has the consequence of an instantaneous increase in the reactor power.

Advantages of an ADS

The main advantages of an accelerator driven system compared to critical reactors are twofold: an ADS allows a greater flexibility with respect to the fuel composition and it has a potentially enhanced safety.

ADS are able to burn fuels that are problematic from the standpoint of critical reactor operation, namely fuels that would degrade neutronic safety characteristics of the critical core to unacceptable levels due to small delayed neutron fractions and short neutron lifetimes. An ADS is capable to cope minor actinide fuel as well as with ^{233}U fuel. Additionally, an ADS allows the use of non-fissile fuel such as thorium without the incorporation of U or Pu (as spike fissile material) in the fresh thorium fuel.

The enhanced safety of an accelerator driven system is due to the fact that once the accelerator is turned off, the system shuts down. When the margin towards criticality is sufficiently large, reactivity-induced transients will never result in a super-critical accident.

Since the accelerator is the driver of the system, the power of the ADS is controlled by the beam current of the accelerator. This feature can be utilized to compensate for the reactivity effect fuel burnup.

In the context of transmutation, another advantage of the ADS is increased core design and fuel management flexibility. The subcriticality also opens opportunities for new reactor concepts, including concepts that are otherwise ruled out by insufficient neutron economy. An ADS allows transmuters to be designed as pure minor actinide burners. This minimizes the fraction of specialized transmuters in the reactor park.

ADS developments in the world

Many ADS concepts have been developed in the world, involving small, medium-size or even large installations ([Kadi and Revol, 2001](#); [Revol, 2001](#)). The first practical attempts to promote accelerators to generate potential neutron sources were made in the late 1940s by E.O. Lawrence in the United States, and W.N. Semenov in the former Soviet Union. During the period 1950s, the MTA (Materials Testing Accelerator) program at Lawrence Livermore investigated in detail the use of accelerators to produce fissionable material. This project was soon abandoned when high-grade uranium ores were discovered in the United States.

A materials production accelerator—the Electronuclear Reactor—was patented in 1960 by Lawrence et al. to provide adequate quantities of material which can only be produced artificially. The targets considered were natural uranium and thorium and the artificially produced materials were ^{239}Pu and ^{233}U respectively. This concept of accelerator breeding was also studied by Russian scientists. A relatively realistic concept of an “Accelerator Driven System” in the present meaning, where safety issues and transmutation of waste play an important role, was also developed in the late 1980s by a research group at Brookhaven National Laboratory.

The Energy Amplifier developed at CERN in the 1990s was devoted to a better use of natural resources and has evolved then to the XADS (eXperimental ADS) developed by Ansaldo Nucleare. At the same time the ADONIS project in Belgium (1995–96) was solely devoted to the production of radioisotopes for the medical industry; ADONIS ([D'hondt et al., 1997](#)) evolved to MYRRHA in 1997; this project still exists and will be detailed in [Section 0](#).

Both XADS and MYRRHA were regrouped in the frame of the EUROTRANS project of the sixth framework program from the European Commission (2005–10). EUROTRANS considered two different but complementary concepts:

- MYRRHA, as smaller scale ADS project for the short term (see below);
- EFIT (for European Facility for Industrial Transmutation), as larger (but still mid-scale) ADS project for the longer term.

EFIT ([Mansani et al., 2012](#)) comprises a large-scale accelerator (800 MeV, 20 mA) coupled to a pure lead target, the subcritical reactor (400 MWth) being also cooled by liquid lead. The optimum burning capacity of such an industrial ADS has been evaluated to be 35 kg MA/TWh leading to a yearly burning capacity, with an availability factor ranging between 80% and 85%, of ~ 100 kg MA/year.

In the meantime (De Bruyn, 2012), the Japanese JAEA was investigating an even larger “commercial-size” installation, with an (1.5 GeV, 20 mA) accelerator coupled to an LBE target, the 800 MWth reactor being also cooled by liquid LBE.

At present time, those large-scale facilities have been put on-hold and attention has been focused on the construction and the operation of smaller installations. A zero-power installation, GUINEVERE, has been successfully operated at SCK CEN, since 2011 in the framework of various research projects of the European Commission.

MYRRHA

Introduction

MYRRHA (Ait Abderrahim et al., 2010), the flexible experimental accelerator-driven system in development at SCK•CEN, will demonstrate the ADS full concept by coupling the three components (accelerator, spallation target and subcritical reactor) at reasonable power level to allow operation feedback, scalable to an industrial demonstrator and allow the study of efficient transmutation of high-level nuclear waste. The MYRRHA-facility is conceived as a flexible irradiation facility, able to work in both subcritical and critical modes. Both modes of operation have their specific energy and flux distributions, which permit, besides transmutation experiments, a wide range of applications, from fuel developments for innovative reactor systems, material developments for GEN IV systems, material developments for fusion reactors, to radioisotope production for medical and industrial applications. Since MYRRHA is based on the heavy liquid metal technology, lead-bismuth eutectic, it will be able to significantly contribute to the development of Lead Fast Reactor (LFR) Technology (see Alemberti, 2021) and in critical mode, MYRRHA will play the role of European Technology Pilot Plant in the roadmap for LFR.

The MYRRHA accelerator

The MYRRHA accelerator is to provide a proton beam with energy of 600 MeV and a maximum current of 4 mA, which will be delivered to the core in continuous wave mode. The beam is delivered to the core from above through a beam window.

High accelerator availability, that is, a long Mean Time Between Failure (MTBF), is commonly obtained by a combination of over-design and redundancy, as well as fault tolerance. Fault tolerance will allow the accelerator to recover the beam within a beam trip (no beam is delivered) duration tolerance after failure of a single component. In the MYRRHA case, the beam trip duration tolerance is 3 s. Within an operational cycle of MYRRHA reactor (90 days) the number of allowed beam trips exceeding 3 s must remain under 10, shorter beam trips are allowed without limitations (Rimpault et al., 2013). The combination of redundancy and fault tolerance should allow obtaining a MTBF value in excess of 250 h.

At present proton accelerators with megawatt level beam power in CW mode only exist in two basic concepts: sector-focused cyclotrons and linear accelerators. Cyclotrons are an attractive option with respect to construction costs, but they do not have any modularity which means that a fault tolerance scheme cannot be implemented. Also, an upgrade of its beam energy is not a realistic option. A linear accelerator, especially if made superconducting, has the potential for implementing a fault tolerance scheme and offers a high modularity, resulting in the possibility to recover the beam within a short time and increasing the beam energy.

The MYRRHA reactor

MYRRHA consists of a pool-type ADS with the ability to operate in critical mode cooled by liquid lead-bismuth eutectic. Consequently, all the primary coolant systems are housed within the reactor vessel. The reactor is located in the reactor pit (Fig. 5) which features a liner able to serve as secondary containment in case of a reactor vessel leakage or break. The reactor cover closes the reactor vessel and supports all the components. The reactor core (Fig. 6) is included in the core barrel and consists of 211 positions. Such positions are filled, among others, with fuel assemblies, control rods, scram rods, the spallation window, in-pile sections, reflector assemblies, instrumentation and surveillance capsules. From these core positions 55 are accessible from the cover and are called Multifunctional Channels (MFC).

The multi-functional channels (MFC) include control rods, scram rods, spallation window target, in-pile sections, instrumentation and surveillance capsules; all installed from the top. Because of the structures above the core, the fuel (driver MOX fuel assemblies as well as MA fuel assemblies) and reflector assemblies have to be loaded from underneath. Thanks to the buoyancy, the fuel and reflector assemblies do not need locking devices to hold them on the core support structure. However, in order to avoid any small position changes of the fuel assemblies inside the core during operation, a core restraint system fixes the radial position of the fuel assemblies.

The MYRRHA reactor core is made of MOX “driver” fuel assemblies with fast reactor typical plutonium content ranging between 30% and 35%. The MYRRHA core is designed to accept up to six fuel assemblies heavily loaded with MA (orange positions in Fig. 6). This MA fuel type is for industrial ADS, such as EFIT mentioned in Section 0; it is composed of 50% Pu, 46% Am, 2% Np and 2% Cm. Cm will not be included in the MA fuel for practical reasons.

Two in-vessel fuel-handling machines, installed permanently in the reactor, handle the loading and the unloading of the fuel assemblies to the in-vessel fuel storages, which are integrated into the diaphragm, the internal reactor structure separating the cold zone of the reactor (down comer) from the hot zone (upper comer). Due to the chosen manipulator concept, the most compact design is obtained by using two independent machines, each covering one half of the core and serving half of the in-vessel fuel

Fig. 5 Overview of the MYRRHA reactor.

Fig. 6 Horizontal cut in the MYRRHA core.

storage positions. The diaphragm separates the cold, high pressure LBE from the hot, low pressure LBE and contains the in-vessel fuel storages and the pump casings.

The diaphragm is connected, together with the cover, to the reactor vessel. The diaphragm consists of two horizontal plates connected to each other by vertical shells allowing some components to reach the lower plenum. Due to this design, several volumes exist in-between the two horizontal plates. Two of these volumes house part of the pumps and the heat exchangers. Each pump casing lodges one pump and two heat exchangers. Four volumes are dedicated for the in-vessel fuel storage. These storages are cooled during operation mainly by the forced circulation of LBE imposed by the pumps, while during shutdown cooling is ensured by natural circulation.

The four primary heat exchangers extract the power of the primary system exchanging it with the secondary system. The head imposed by the pumps circulates the hot LBE from the hot plenum into the heat exchangers. After being cooled, the LBE flows into the pump casings and then through the pumps themselves. This concept mitigates the LBE corrosion by reducing the temperature of the fluid inside of the pumps. In particular, these are sized in order to be able to pump the LBE through the core balancing also the head losses of all the other sections of the primary system. The number of heat exchangers and pumps is optimized taking into account the space utilization inside the reactor vessel and the symmetry of the coolant flow. This leads to a configuration with two heat exchangers and one pump on each of the two sides of the reactor.

R&D in support to design and licensing

SCK CEN conducts since the beginning of the program an ambitious R&D program to address the main design and licensing challenges. In this frame SCK CEN has constructed and commissioned various LBE test facilities which are used for qualification of the key materials and components of MYRRHA. These facilities can also be used for the development of materials and components for fast reactors of all power ranges, including SMR type systems, working with LBE or Lead as coolant.

The main challenges of the MYRRHA development are in particular related to the use of liquid Lead-Bismuth Eutectic as reactor coolant. Consequently various LBE test facilities for research on

- heavy liquid metal chemistry and conditioning,
- heavy liquid metal corrosion of materials,
- thermal hydraulics in heavy liquid metals,
- instrumentation in heavy liquid metals, and
- testing of components in heavy liquid metals

have been constructed and commissioned (Fernandez et al., 2019).

For the components and thermal hydraulics program the *E*-SCAPE facility, European SCALe Pool Experiment, a thermal hydraulic 1/6-scale model of the MYRRHA reactor, has been commissioned in spring 2017. The main objective of this installation (Fig. 7) is the study of the thermal hydraulic behavior of liquid metal in a complex pool geometry. The characterization of the pool thermal hydraulic phenomena is needed for qualification of computational fluid dynamics code and other system tools used for the safety assessment of a reactor system.

The COMPLIT, COMPOnents LOOp Testing, facility is a large-scale, closed loop isothermal experimental loop in operation since 2014, used for hydraulic experiments of full-scale reactor components in flowing LBE. The goal of COMPLIT is to simulate a full-scale hydraulic flow path through the MYRRHA core allowing the characterization of hydraulic and hydrodynamic behavior of full-scale MYRRHA core components such as the fuel assembly, the spallation target, the control and safety rod systems and other in-pile instrumentation, systems and experiments.

HEXACOM, Heat EXchanger at COMplot, steam loop is a two-phase water-steam cooling circuit that provides temperatures and flow conditions representative of the MYRRHA Secondary Cooling System. The main objectives of the facility is to investigate the heat transfer performance of different primary HX configurations within the operational ranges relevant to MYRRHA, to develop and validate heat transfer correlations specific to bayonet tube applications in flowing LBE, to improve the level of knowledge on the phenomena that occur in the steam/water side of double wall bayonet tube heat exchangers that operate at low pressure,

Fig. 7 Overview of the *E*-SCAPE facility.

to obtain experimental data suitable for model development and/or the validation and verification of system codes. Since HEXA-COM is a small version of the MYRRHA secondary and tertiary system, additional phenomena, typical for steam/water, natural circulation cooling and anti-freezing strategies can be studied in support of the design of these systems in MYRRHA.

Finally, RHAPTER, the Remote HANDling Proof-of-principle TEST Rig, in operation since 2011, is designed to test and validate mechanical components submerged in LBE.

The LBE chemistry and conditioning program uses the MEXICO, Mass EXchanger In Continuous Operation, loop to test different oxygen control systems, such as the gas phase, solid oxide phase and electrochemical oxygen pumping systems for regulating dissolved oxygen in liquid lead-bismuth eutectic. It is also used to evaluate the efficiency and expected life time of filtration systems for purifying the LBE of oxides and possible impurities from the liquid metal flow while minimizing the created heavy metal waste stream.

HELIOS, HEavy Liquid metal Oxygen conditioning System, is a LBE conditioning and storage setup which is used to investigate LBE conditioning schemes. It can also serve to study calamity mitigation strategies after a possible steam ingress due to a tube rupture in a heat exchanger or exposure to air.

The main infrastructure for materials research is CRAFT, Corrosion Research for Advanced Fast reactor Technology. It is an installation for long term corrosion experiments on MYRRHA candidate materials in liquid LBE. The loop type installation operates at representative conditions of temperatures, LBE velocities and dissolved oxygen concentrations of MYRRHA.

LIMETS, Liquid METals Test Stands, are experimental set-ups designed for mechanical testing of materials in a stagnant LBE environment in order to investigate mechanisms and kinetics of material-liquid metal interactions that influence the mechanical properties of materials.

Conclusions

Partitioning and transmutation is an attractive solution to reduce the amount of long-lived radioactive waste legacy and to reach the goal of sustainable nuclear energy systems. P&T could address the high-level radioactive waste issue and initiates the strategy towards a more resource-efficient nuclear energy system in the future. P&T will not replace the need for appropriate geological disposal of high-level waste, but it will reduce the long-term radiotoxicity of the waste significantly and thus reduce the burden of HLW on the safety and required volume of geological disposal increasing highly its acceptability by the public.

All transmutation strategies with closed fuel cycles could achieve high reductions in the inventory of actinides and the radiotoxicity of the nuclear waste by making use of fast neutron spectrum systems such as fast critical reactors or accelerator driven systems.

Nevertheless, the sub-critical ADS offers more degrees of freedom with respect to the core design and fuel management as well as flexibility in the policy towards the use of nuclear energy.

With the extensive development of accelerator technology, it appears today that proton beam powers of 10–100 MW with the needed reliability for operating ADS systems are within the reach in the coming decade using the LINAC technology.

Introduction

While many think of nuclear reactors only as a source of power for electricity generation or propulsion, there is a distinct class of hundreds of remarkable reactor systems that use the sustained fission chain reaction to produce neutrons and gamma radiation for scientific experiments and/or to transmute target isotopes into medical or industrial isotopes (IAEA, 2014).

The range of science and isotope production research reactors provide is not just broad, but touches our lives in many ways every day (DOE, 2020; Barradas, 2021). Small reactors may focus on education and training, but they also allow tracking of environmental pollution or industrial quality control for industries like insect-resistant lumber or mold-resistant drywall. Larger reactors allow experiments in the core to study how neutron and gamma radiation damage materials, testing new fuels or core components, and assuring safety of power reactors and facilitating space applications of materials. In addition to making isotopes that detect and fight cancer, research reactors also produce large semiconductor materials vital to hybrid electric cars. And since neutrons do not have any electric charge but do have magnetic spin, scientists in many fields can use beams of neutrons delivered from the reactor core to study details of materials and biological processes in unique ways complementary to X-rays.

The three core images of Fig. 1 hint at the tremendous variety of research and test reactors. The RA-6 research reactor in Argentina uses fuel in the form of flat plates grouped into “elements” (i.e., a set of plates secured in a support structure) that are placed on a grid plate at the bottom of an open pool. The MARIA reactor in Poland uses fuel elements in which each plate is curved so that the elements are a set of concentric circles. The MARIA elements are sealed into individual cooling loops, and it is the loops that are loaded onto the grid plate at the bottom of a pool. The KUCA critical facility dry cores use small “coupons” of uranium sealed in epoxy that are stacked as combinations of fuel, polyethylene plastic, and spacers or test materials.

International nuclear security requires keeping weapons-usable material out of the wrong hands. Many of the research reactors in the world have used fuel composed of High Enriched Uranium (HEU, U-235 enrichment $\geq 20\%$) (NAS, 2016). The HEU fuel provided the density of the fissile isotope U-235 needed with the types of fuels available at the time the systems were designed and deployed. However, as described by Glaser (2006), the risk of misuse of fuel increases with enrichment. National and international norms treat uranium with an enrichment of the isotope U-235 $\geq 20\%$ as a security risk that should be minimized, and to the extent possible eliminated, for civilian reactors and medical isotope production.

The process of changing the fuel used by the reactor from HEU to Low Enriched Uranium (LEU, U-235 enrichment $< 20\%$) is defined as reactor conversion. The US technical effort to convert began in 1978 as the Reduced Enrichment for Research and Test Reactors (RERTR) program. From the beginning, the effort organized a global community of reactor operators, fabricators, and their governments.

As described at the first RERTR International Meeting in 1978 (Travelli, 1978), the program has been focused upon preservation of reactor mission capability as a central tenet of the conversion program. Indeed, the reason the reactor conversion program continues forty years later is because the community continues to collaborate on projects to preserve mission capability, rather than forcing degradation of performance. The RERTR program management within the Department of Energy (DOE) matured to the Global Threat Reduction Initiative (GTRI, 2004–15) and now the National Nuclear Security Administration (NNSA) Office of Material Management and Minimization (M3, 2015–present).

As indicated in Fig. 2, there has been a great deal of success converting reactors around the world. A total of 71 reactors converted from HEU fuel to LEU fuel in the period 1978–2019, and an additional 31 reactors that used HEU fuel have been confirmed permanently shutdown. Fig. 2 highlights the fact that 24 high impact reactors with thermal neutron fluxes in experimental positions higher than 10^{14} n/cm²/s have been converted without significant reduction of the maximum available fluxes.

Challenges and Approaches to Reactor Conversion

Converting a reactor while maintaining experimental performance is not an easy task, but it is an exciting technical challenge.

Nearly all of the fissions in a uranium fueled reactor occur in the isotope U-235. So if the enrichment is reduced from 93% U-235 to 19.75% U-235, the density of uranium in an unchanged geometry would need to be increased by at least a factor of 4.7. In fact, most uranium that is not U-235 is the isotope U-238, which is more likely to absorb a neutron without fission than to fission. That means U-238 acts as a “parasitic” absorber, reducing the number of neutrons available for fissions and experiments, so the overall LEU uranium density would need to increase by more than 4.7 if the geometry is not changed. Because of this, the search for fuels with different uranium alloys that have higher density than the original HEU fuels has been a major focus of the reactor conversion effort.

Fortunately, the many minds around the world that have worked on reactor conversion found ways to apply physics of core modifications in addition to uranium density to preserve experimental performance. For instance, changes of the fuel geometry, reflectors, and mix of fresh and partially-used fuels within an existing reactor adjust the core volume and the energy of the neutrons that interact with the uranium and experiments.

Changing the geometry of fuel and/or core does mean that the cooling of the fuel is changed. Adequate cooling is the main constraint for how small a core can be made and how intense local experimental fluxes can be. So the computational methods that predict the details of where power is produced in the reactor core over time and the methods that predict how the associated heat is removed have been continuously improved over the decades, with experiments to verify that the methods predict details of reality well.

Changing the fuel materials and geometry also requires the manufacturing of fuel to be improved over time, with enhanced precision, predictability and quality verification methods.

No two conversions have been the same since each research reactor is unique in design, mission, and/or operational cadence. Global collaboration through the International Atomic Energy Agency (IAEA), bilateral, and multilateral teams has always been vital to address both technical challenges and the logistics/legalities of the multinational nuclear fuel cycle (particularly the transportation aspects of the fresh fuel supply chain and spent fuel repatriation).

Reactor Conversion Historical Overview by the Decades

Fig. 3 restates the progress of global reactor conversion in terms of geography and time. It is clear that international cooperation existed from the start, but then accelerated as improvements to fuels, methods, and collaboration structures all improved with time.

1978–87: Pragmatism

Ten conversions were accomplished in seven countries during the first decade of the program by:

- Conversion to UAl_x and U_3O_8 fuels fabricated with higher uranium density than had originally been deployed. This approach could only suffice for a few reactors, but showed the importance of fabrication improvements.

* Cumulative number of conversions to LEU (71) + shutdowns confirmed prior to shutdown (31) in the years 1978-2019

Fig. 3 Global reactor conversion progress. Source: John Stevens, Argonne National Laboratory.

- Conversion of HEU plate-type cores to low-density LEU TRIGA UZrH rod clusters. This was a clear demonstration of how physics-based modifications beyond simple density would allow conversion.

The US Nuclear Regulatory Commission (NRC) issued regulation 10 CFR 50.64 in 1986, formalizing the expectation of the use of LEU fuels in civilian reactors once the ability to preserve acceptable experimental performance is demonstrated with an “acceptable fuel,” and funding to perform the conversion is provided.

LEU TRIGA 20/20 & 30/20 UZrH fuel was qualified by the US NRC in 1987 (where the 20/20 indicates 20 weight percent uranium in the UZrH at 20% enrichment U-235, 30/20 indicates 30 weight percent uranium in the UZrH). These higher density UZrH fuels had reactivity similar to the prior TRIGA HEU fuels to facilitate TRIGA reactor conversions.

1988–97: Momentum and Improved Methods to Open Design Space

Twenty conversions were accomplished in 12 countries during the second decade of the program.

The most significant breakthroughs included:

- U_3Si_2 fuel was qualified by the US NRC in 1988.
- The “Schumer Amendment,” Section 903 of the Energy Policy Act of 1992 formalized restrictions on exports of HEU from the US related to the expectation to convert to LEU.
- The US NRC published NUREG 1537 “Guidelines for Preparing and Reviewing Applications for the Licensing of Non-Power Reactors” in 1996, specifically addressing the scope of safety analysis expected for a reactor conversion.
- U_3Si_2 and TRIGA LEU 20/20 and 30/20 fuels were deployed to a variety of reactors.

Many methodological improvements for design, operational, and safety analyses were pursued during the second decade in order to reduce the penalties of overly “conservative” approaches. The improved methods evolved to treat physics detail, replacing linearizations, assumptions of separability, and correlations wherever possible.

- Neutronics
 - o Improved Cross-Sections for Deterministic Steady State and Depletion Calculations
 - o Monte Carlo methods (e.g., MCNP) to replace steady state deterministic methods 1990–now (Fig. 4 illustrates MCNP models for two very different research reactor cores)
 - o Monte Carlo-based Depletion (1998–now)
- Thermal-Hydraulics methods have been extended to treat multiple dimensions and to apply less conservative safety margin correlations that have been shown more appropriate to distinct research reactor flow conditions.
 - o PLTEMP steady state analyses (1985–now)
 - o PARET transients (1982–now)
 - o RELAP system transients (1996–now)
- Fuel Performance Modeling: both Correlation-based and Finite-Element methods evolved as irradiation test data were collected for each of the new fuel systems.
- Linkages & Automations between physics domains and levels of detail have been established. For instance, historic separability assumptions between “Pin Cell” and the core have been replaced by more Full-Core and Full-System analyses in order to avoid conservatism or potential errors of a priori judgements about how the power distributions and cooling interact.

1998–2008: Celebrating Successes, Sobered by 9/11

Twenty-six conversions were accomplished in 19 countries during the third decade of the program. An additional four shutdowns-prior-to-conversion were confirmed in three countries.

Fig. 4 Examples of research reactor core models. Source: John Stevens, Argonne National Laboratory.

The pace of conversions was accelerated in response to the terrorist attacks of 9/11 in 2001. Eight conversions had occurred in the four years 1998–2000. The Global Threat Reduction Initiative (GTRI) was formed in 2004. The associated budget increases, improved project management, and global cooperation after GTRI was formed led to eighteen conversions in the 5 years (2004–08).

Collaboration between East and West on conversion of reactors exported by Russia and China was a major breakthrough after 9/11. While there had been productive engagement on nonproliferation matters for years, new frameworks were established in the third decade. The Russian Research Reactor Fuel Return (RRRFR) program was launched in 2001 to repatriate Russian origin HEU, analogous to the US Foreign Research Reactor Spent Nuclear Fuel Acceptance Program that had begun in 1996.

Synergistic Working Groups for several “sets of similar reactors” were established to accelerate conversion projects and improve efficiency of supply. The TRIGA conversions (both original TRIGA and Plate-Type to TRIGA) had shown the benefits of the working group approach.

The Miniature Neutron Source Reactors (MNSR) exported by China to five countries were identified as a clear “set” with single supplier and very similar technical issues. While each MNSR has a distinct regulator, political, and logistical matters, those project aspects would benefit from the creativity and “lessons learned” of their peers. The MNSR working group approach was vital due to the nuclear political complexities of United States and European technical collaboration with some of the countries involved (China, Ghana, Nigeria, Pakistan, Syria, and Iran). An IAEA Coordinated Research Project for MNSR conversions was established in 2006 that helped lead to several subsequent conversions (2016, 2018, and 2019 in China, Ghana, and Nigeria).

Russian designed reactors that used IRT fuel (concentric extruded tubes of fuel) in Russia and abroad were another group able to benefit from common IRT-3M or IRT-4M fuel qualification efforts, and analytical collaborations. The Czech VR-1 was converted in 2006. The Libyan IRT-1 critical facility and reactor were converted in 2006 and 2007. The Uzbek VVR-SM was converted in 2008. The Czech Rez reactor converted in 2010.

Two large and enduring working group structures were established to address the most challenging Western research reactor conversion projects, those reactors that could not use any prior qualified LEU fuel to convert while maintaining their critical missions.

- US High Performance Research Reactors (USHPRRs): The MITR at Massachusetts Institute of Technology in Cambridge, Massachusetts; the MURR at University of Missouri in Columbia, Missouri; the NBSR at the National Institute of Standards and Testing (NIST) in Maryland; the ATR at the Idaho National Laboratory (INL); and the HFIR at Oak Ridge National Laboratory (ORNL) in Tennessee. (The ATRC critical facility will also be converted to remain appropriate for the ATR reactor programs). The NNSA USHPRR sub-program that began in 2005 has assembled expertise from nine national laboratories and sites (Argonne, Brookhaven, Idaho, Los Alamos, Oak Ridge, Pacific Northwest, Sandia, and Savannah River national laboratories and the Y-12 national security complex) as well as the reactor operating institutions, fuel fabricator BWXT, and the US NRC.
- European High Flux Reactors (EUHFR): the BR2 at SCK CEN in Mol, Belgium; the RHF at Institut Laue-Langevin (ILL) in Grenoble, France; and the JHR under construction at the French Alternative Energies and Atomic Energy Commission (CEA) in Cadarache, France; and the fuel fabricator Framatome CERCA. The US technical effort to support the EUHFR conversion group that began in 2008 has always involved a team of Argonne and Idaho National Laboratories, under the International Reactor Conversion sub-program at NNSA. The Y-12 national security complex has been instrumental for fresh uranium supply and transport. Savannah River National Laboratory provides strategic assistance.

2009–19: Tackling Ongoing Challenges Together

Fifteen conversions were accomplished in 12 countries during the fourth decade of the program. An additional 27 shutdowns-prior-to-conversion were confirmed in 13 countries.

The decade saw the fruition of several projects that had taken more than a decade due to the combination of fuel qualification and fabrication improvements, newly optimized designs and the associated safety analyses, and complex supply chains and transportation logistics:

- The global TRIGA Conversion Scope was completed—the first class of reactor conversions to be successfully completed.
- The Russian-domestic ARGUS reactor converted.
- Three of the seven MNSR reactors converted, with the technical path for the remaining four well defined (if not the political/financial path).
- The VVR-K in Kazakhstan converted, and the success of that multinational project has facilitated the IVG project expected to be completed in 2021.

An impressive span of multilateral projects demonstrated continued resolve to address the full range of challenges for remaining conversions with creative persistence. The tradition of operators and nations that successfully converted helping their peers—or even competitors—to successfully convert continued. For instance, the SLOWPOKE reactor at Polytechnique Montreal in Canada converted in 1997, but their experts were vital to the success of the JM-1 SLOWPOKE conversion in Jamaica in 2015. Similarly, a number of the technical experts helping to implement the Arak Modernization Project of the Joint Comprehensive Plan of Action (JCPOA) “Iran Agreement” leveraged reactor conversion expertise in reactor design, fuel qualification, and multinational project implementations to modernize the Iranian IR-40 reactor as a system with much higher experimental performance, but much lower risk of proliferation.

The Continuing Effort to Achieve High Performance With Low Risk

The decade before us will see some of the most exciting reactor conversions in terms of both the technical accomplishments and the impact toward minimization of HEU in civilian use.

In 2021 and 2022 the IVG in Kazakhstan and the KUCA in Japan should both convert after successfully implementing reactor-specific LEU fuel qualification.

Table 1 indicates the variety of research reactor fuels used in reactors that have converted or that are under development and qualification for conversion of the remaining reactors. The fuel qualification and fabrication campaigns described in DOE (2020) will allow the USHPRR and EUHFR reactors to convert in the 2026–34 timespan.

The global team does also continue to develop and apply higher-fidelity multiphysics methods for design and safety analysis. The combination of high density fuels, supply chain, methods, expertise, and implementation skills that the reactor conversion program has developed and deployed will surely be leveraged to assure high experimental performance, safety, and low risk of proliferation for the new research reactors of the future.

Acknowledgement

As noted above, the reactor conversion effort has always been collaborative. The technical “giants” that paved the way to conversion include Armando Travelli, Jim Snelgrove, Jim Matos, Bill Woodruff, Pablo Adelfang, Jordi Roglans, and many more. The IAEA has been an important partner to the 43 countries in which conversions have occurred. The community of technical and policy experts have met at 40 RERTIR International Meetings hosted by 21 countries. We are grateful that those that have converted in the past continue to assist the global effort to complete the remaining conversions. Argonne’s reactor conversion work is sponsored by the US Department of Energy, Office of Material Management and Minimization in the US National Nuclear Security Administration Office of Defense Nuclear Nonproliferation under Contract DE-AC02-06CH11357.

Table 1 Uranium density of research reactor fuels qualified and under qualification.

	Uranium loading density (gU/cm ³)			
	1978 (Travelli, 1978)	Now (Travelli, 1995)	In Progress	
TRIGA				
U ₂ ZrH pins	0.5	2.1	–	30/20 ^a qualified in NUREG-1282 (1987)
UO ₂ pins	9.3	–	–	Not fabricable for plate geometry

Glossary

Activation Analysis A method to identify an unknown material by irradiating it with neutrons and measuring the characteristic radiation from the reaction products.

Alpha Particle A positively charged particle emitted by certain radioactive material, made up of two neutrons and two protons (a helium nucleus).

Beta Particle A negatively charged particle (a high-speed electron) emitted in certain types of radioactive decay. Some types of these particles have a positive charge and are called positrons.

Deuterium A nonradioactive isotope of hydrogen having one proton and one neutron in its nucleus.

Fission The process of splitting a heavy atom into two or more lighter atoms, usually upon absorbing a neutron.

Fusion Fusing two light nuclei into one heavier nuclei.

Gamma Ray A high-energy, short-wavelength electromagnetic radiation emitted in the radioactive decay of many nuclides. Gamma rays originate from within the nucleus.

Ionizing Radiation Radiation capable of causing ionization of the atoms through which it travels.

Irradiation The result of nuclear radiation impinging upon a material.

Isotope An atom of the same element but with a different mass number. Isotopes of a given element have the same number of protons but a different number of neutrons in their nuclei.

MeV Million electron volts = amount of kinetic energy gained by an electron that is accelerated, in a vacuum, across an electric potential difference of one million volts. $1 \text{ MeV} = 1.602 \times 10^{-13} \text{ J}$.

Neutron A basic particle residing in the nucleus of an atom that is electrically neutral. It has a mass approximately equal to a proton.

Nuclear radiation The process in which an unstable atomic nucleus loses energy by emitting nuclear radiation – usually gamma-rays, beta particles or alpha particles.

Nuclide A species of atom characterized by the number of protons, number of neutrons, and energy content of its nucleus.

Photon A quantum of electromagnetic radiation of energy $h\nu$ (h being Planck's constant and ν the frequency of the radiation).

*Retired.

RHU Radioisotope heater unit.

RTG Radioisotope thermoelectric generator.

Sievert The international unit used for measuring effective radiation dose: the health effect of ionizing radiation on the human body. (1 Sievert = 100 Rem).

T_{1/2} Half-life of a radioactive substance (the time when only one-half of the original substance is still in existence).

Transmutation The process of changing one isotope into another isotope through irradiation with neutrons.

X-Ray Electromagnetic radiation of energy greater than that of visible light. X-rays emanate from outside the nucleus.

Introduction

Welcome to the section of this encyclopedia dealing with the myriad applications of harnessed nuclear radiation not directly related to the production of nuclear power. Whereas nuclear power is generally recognized as the most obvious application of nuclear technology, a relatively unknown fact is that non-power applications resulting from the incredible discoveries of Wilhelm Roentgen, Henri Becquerel, Marie Curie and their successors far outdistance nuclear power in terms of the number of jobs created and the financial contribution to national economies (Waltar, 2004, 2021; Bezdek, 1994, 2021).

Radiation technology has already delivered enormous contributions to medicine, agriculture, modern industry, environmental protection, public safety, and cultural heritage, and the future continues to look very bright for the broadening of these applications to benefit our ever-growing global population. This section of the encyclopedia is dedicated to a review of the variety of contributions of radiation technology and their impact to modern life. In order to cover the extensive spectrum of radiation applications in a coherent manner, the following chapters have been generally grouped according to the categories just mentioned.

Medicine

Of the various areas of where radioisotopes have been used in our modern world, medical applications are among the earliest and the most widely known. Shortly after the discovery of artificial radioactivity in 1934 by Frederic and Irene Joliot (Irene being the daughter of Pierre and Marie Curie), medicine began to benefit from the atom. One of the first uses was Iodine-131 for the treatment of thyroid cancer—followed by a phenomenal growth of diagnostic and therapeutic applications, along with new drug developments. Nuclear reactors and particle accelerators soon came along to produce a wide variety of radioisotopes capable of emitting alpha, beta, and gamma particles—as well as neutrons for specialized cases. Radioisotopes are now in common use for both diagnostic and therapeutic purposes.

We begin this section on medicine with the applications of radiation technology to sterilization, followed by four chapters on nuclear medicine.

Chapter 2: Medicine: Sterilization (Kalia, 2021) focuses on the use of radiation techniques to sterilize most of the surgical supplies readily available at hospitals or medical clinics. The original processes utilized to ensure sterility were based on chemical or heat treatments. But once radiation processes were developed, radiation has generally become the preferred treatment modality for sterilizing bandages, syringes, and other materials commonly used.

Chapter 3A: Medicine: Radionuclides Used in Nuclear Medicine (Venkatesh and Kang, 2021) provides a broad perspective on the numerous radionuclides used for nuclear medicine diagnostic and therapeutic procedures. Specialty radioisotopes using either X-rays, negative or positive beta rays, or gamma rays at low doses are employed in SPECT or PET devices for imaging the site of malignancies during diagnostic procedures, whereas high-energy radiation is deployed in high doses for therapeutic uses. One out of every three patients entering US hospitals or medical clinics benefit from nuclear medicine for either diagnostic or therapeutic purposes.

Chapter 3B: Medicine: Radiopharmaceuticals and Their Use in Nuclear Medicine (Kang and Venkatesh, 2021) is the specialty in which a radiolabeled substance known as a radiopharmaceutical is administered into the patient (“in-vivo”) either for diagnostic or therapeutic purposes. Since the behavior of the radiopharmaceuticals inside the body is governed by the biochemistry of the radioactive molecule and the biochemical functioning of the concerned body organs, nuclear medicine studies provide unique functional information unlike most other imaging modalities. Thus, nuclear medicine imaging is also referred to as functional imaging or molecular imaging. Studies that analyze a patient’s sample outside the body, such as determining for tissue malignancy, are referred to as “in-vitro.”

Chapter 4: Medicine: New Drug Developments (Venkatesh and Korde, 2021) provides the basis for the development of many new drugs coming on the market that require the employment of radiation tracers in order for both the researchers and the licensing agencies to certify that the new drug is reaching and treating the intended target tissue, while minimizing any damage to surrounding healthy cells. Approximately 80% of all new drugs rely on radiation tracer technologies before being approved by the FDA for commercial use.

Chapter 5: Medicine: Therapeutic and Other Applications Using Sealed Radiation sources ([Shrivastava and Venkatesh, 2021](#)) articulates the use of sealed radiation sources for the treatment of cancer. External (outside the body) focusing of radiation on cancerous lesions is known as Teletherapy, whereas Brachytherapy is accomplished by placing the sealed sources in close contact with the lesion (inside the body). These, and other therapeutic techniques using sealed radiation sources, constitute the focus of this article.

Agriculture

Chapter 6: Agriculture: Improving Crop Production ([Sivasankar et al., 2021](#)) reveals the incredible impact of how X-ray, beta, gamma, and neutron irradiation have transformed the food industry. Adequate supplies of food are absolutely critical to the health and actual survival of global citizens. Though not widely known, perhaps the largest impact of harnessed radiation is in the field of agriculture. Well over 200 new varieties of grains and vegetables have been developed using such irradiation techniques to improve crop production with wheat, rice, and cotton leading examples of enhanced, world-wide commerce. Radiation sources harnessed to improve the efficient utilization of both fertilizers and water have saved enormous quantities of these precious resources.

Chapter 7: Agriculture: Improving Livestock Production ([Viljoen et al., 2020](#)) reveals how radiation sources have been employed to enhance the attributes of a huge variety of animal stock. Included is a description of the methods deployed to improve the digestion of food intake, the development of vaccines, and the eradication of harmful insects.

Chapter 8: Agriculture: Electron Beam Irradiation Technology Applications in the Food Industry ([Pillai and Pillai, 2021](#)) details methods currently in global use to preserve food that would otherwise be wasted. Despite new radiation technologies now available to enhance both plant and animal production, a huge volume of farm products spoils before reaching the kitchen table. Hence, preserving the food that has been produced is becoming more essential for everyday commerce, considering the continually expanding global population and the necessity for extending the shelf life of so many perishable products. Food irradiation is now more prevalent in the kitchen than normally recognized—providing sanitized spices and even those special encapsulated coffee creamers that do not require refrigeration.

Modern industry

Chapter 9: Modern Industry: Diagnostics and Process Control ([Thereska and Brisset, 2021a](#)) focuses on the myriad uses of radiation thickness and density gauges to monitor the production of everything from paper production to the control of concrete pours in construction. It is difficult to imagine modern life without the application of radiation techniques to so many products that we now almost take for granted.

The next three chapters focus on nuclear techniques for the testing and inspection of new materials as they become available on almost a daily basis:

Chapter 10: Modern Industry: Gamma Methods for Materials Testing and Inspection ([Bjornstad, 2021a](#)) focuses on the unique properties of gamma irradiation for testing and inspection.

Chapter 11: Modern Industry: Neutron Basic Interactions, Sources and Detectors for Materials Testing and Inspection ([Bjornstad, 2021b](#)) provides a detailed overview on how neutron sources are developed, along with appropriate detection techniques, for use in testing and inspection.

Chapter 12: Modern Industry: Applications of Neutrons for Materials Testing and Inspection ([Bjornstad, 2021c](#)) provides vast coverage on how neutrons are utilized for materials testing and inspection.

Chapter 13: Modern Industry: Development of New Materials ([Fulvio, 2021](#)) focuses on the application of radiation technology to develop a myriad of new products that enter our market on a frequent basis—products all the way from kitchen conveniences (e.g., shrink wrap created by radiation cross-linking) and the semiconductors that provide the key ingredient of our computers and cell phones.

Chapter 14: Modern Industry: Non-Nuclear Power Applications ([Thereska and Brisset, 2021b](#)) provides an overview of how radiation techniques are applied to the fossil fuel industry (coal and oil) and the renewables (solar, wind, and geothermal). Whereas the bulk of this encyclopedia is properly focused on nuclear energy, it is noteworthy that radiation techniques have enormous applications to the development and utilization of sources of energy not tied to nuclear power.

Chapter 15: Modern Industry: Personal Care, Conveniences, & Safety ([Waltar, 2021](#)) is included to reveal the numerous ways that radiation devices are employed to provide for our personal comfort and care—from smoke detectors to the brilliant colors of precious gems.

Environmental protection

Chapter 16: Environmental Protection: Managing Fresh Water Resources ([Kumar and Ansari, 2021](#)) is focused on perhaps the most pressing global challenge today; namely, finding ways to discover, guard, and produce adequate supplies of potable

water—especially for those areas of the globe where fresh water is rapidly vanishing. There are likely many people who would be surprised by how many ways radiation is used to protect and improve our precious environment.

Chapter 17: The Oceans—Formation and Global Climate Change (Hong and Povinec, 2021a) focuses on the formation and significance of our oceans to life on our planet—and how natural contamination takes place. It is continually becoming clear that it is essential to protect the greatest water mass in the world; namely the oceans.

Chapter 18: Environmental Protection: The Oceans—Implications of Man-Made Contamination (Hong and Povinec, 2021b) continues the background provided in Chapter 17 by focusing on how modern life continues to contaminate our precious oceans, and why we need to utilize radiation devices to detect and remove pollutants that could significantly alter the productivity of these massive reservoirs of water.

Chapter 19: Environmental Protection: Reducing Environmental Pollution (Chmielewski et al., 2021) reveals the many ways our current population continues to pollute our only life-giving planet. It is very important, therefore, to determine the sources of pollution and the remedies for reducing and cleaning up such sources.

Public safety and security

Chapter 20: Public Safety and Security: Border Security (Patton, 2021) is focused on the radiation technologies currently in use to make sure the massive daily quantity of goods entering our ports around the world do not contain illicit materials. We all now live in an increasingly fragmented world. Every day we hear of new threats to our desired way of life, and we need assurances that we are being protected.

Chapter 21: Public Safety and Security: Emerging Inspection Techniques—Active Interrogation for Nuclear Materials (Strellis and Gozani, 2021) provides an overview of how even more powerful radiation techniques can be developed and used to thwart the increasingly sophisticated intentions of terrorists and others with criminal intentions.

Chapter 22: Public Safety: High Radiation Sources (Starovoitova, 2021) is included to help us all understand both the benefits of properly employing high radiation sources, along with the precautions necessary to minimize any wrongdoing. Although radiation can, indeed, be very harmful if delivered inappropriately in high doses, that same feature can and is being used very effectively to kill cancer, eradicate harmful insects, and greatly extend the shelf life of perishable food products.

Chapter 23: Public Safety and Security: Nuclear Forensics (Fedchenko, 2021) describes some of the most interesting uses of radiation to help solve crime scenes. Included is both the history of how radiation has been used in criminal investigations, as well as a description of some evolving new technologies to make further use of these unique capacities.

Cultural heritage

Chapter 24: Cultural Heritage Preservation (Varquez and Nagai, 2021) is included to provide insight on how precious works of art can be protected against both natural degradation processes as well as intentional forgery. History is very important to all segments of our global population, and having ways to understand our history, and the associated artifacts, provides a precious contribution to fulfilled living.

Chapter 25: Global Market for Radiation Applications (Bezdek, 2021) is a most fitting way to conclude this section. It provides an assessment of how incredibly important this “silent servant” is to modern life, etc. and an assessment of how the global market for radiation applications continues to grow. Data indicate the growth ranges from 5% per year to over 20% per year, depending upon the sector—with a current contribution of over 500 billion US dollars to our global economy. As such, both the number of jobs and the economic impact of radiation applications—NOT DIRECTLY CONNECTED TO THE PRODUCTION OF HEAT AND ELECTRICITY—widely exceed the comparable numbers associated with nuclear power production. Marie Curie can be rightly proud of the legacy she created when she first discovered and coined the term “radioactivity!”

So how is this all done? How can radiation, which cannot be seen, heard, or felt, accomplish such enormous tasks? To the uninitiated reader, this may be very difficult to grasp. Hence, before moving on to the remaining 24 chapters in this section that cover these many applications in considerable detail, the present chapter will be focused on some of the unique characteristics of radiation that allow it to be such a helpful servant. This requires defining the “hooks” upon which to fasten the harness.

Our forefathers have known for centuries that oxen and horses possess strength far beyond that of humans. Consequently, they built harnesses to translate their energy into pulling plows and to perform other useful work. Chemical energy, originally exploited in campfires for heating caves and cooking meals, has been recognized to have explosive characteristics when certain fuels are mixed. This “hook” gave rise to the internal combustion engine—allowing tractors of enormous “horsepower” to considerably increase efficiency on the farm. This same internal combustion engine continues to be the primary source of power widely used today for cars, trucks, ships, and locomotives. Early observations that electrons could be directed to move in a preferred direction by applying a voltage to one end of a conductor has given rise to vacuum tubes and then computer chips capable of transmitting almost unfathomable amounts of data in modern computer systems.

As we now look to radiation, we find that there are over a dozen unique aspects of nuclear radiation and of radioactive decay process that can be and have been tapped and harnessed for beneficial human use.

Material penetration

Different types of particles are emitted during the radioactive decay process and they have unique material penetration powers. For instance, if a beam of gamma rays of a known energy is focused upon a thin sheet of aluminum, the precise thickness of that sheet can be determined by measuring the reduction in the beam current on the other side of the metal. This property (also referred to as attenuation) is used in countless commercial operations such as making rolled metals or paper, filling containers, and so on (Fig. 1).

The most commonly recognized application of radiation penetration, and its associated attenuation property, is for imaging. A perfect example is an ordinary dental X-ray. Here the dentist focuses an X-ray beam on one side of the patient's mouth and places a film on the other side of the tooth. That's the little "wad" that we are asked to bite down on and then hold still. As the X-ray traverses the area of the tooth, it easily penetrates through the gum and exposes the film. But the tooth is more massive, and very little of the X-ray can penetrate. Hence, that area of the film is not exposed. Should there be a cavity in the vicinity, a bit more of the X-ray can get through to the film. Hence, a "gray" spot appears at that point—and the dentist then knows precisely what to do.

X-rays are also commonly used to check the health of lungs (chest X-rays), as well as to assist the orthopedist should the patient have the misfortune of breaking a bone somewhere in his or her body. The amount of radiation normally received from such procedures is now quite small (a few micro Sieverts) and certainly worth it. Most people would not want the dentist to pull the wrong tooth or to have a broken bone set improperly.

Extensive use of X-rays, gamma rays, and beta particles to measure thicknesses, densities, etc. in a myriad of medical and industrial processes are covered by (Venkatesh and Kang, 2021; Thereska and Brisset, 2021a). Modern industry simply would not be able to function without the employment of this material penetration attribute of radiation technology.

Heat source

Alpha and beta particles are stopped within short distances of their origin as they collide with atoms in their surrounding material, thus converting their initial kinetic energy into heat. Substantial heat is generated in this process, much like the heat generated in a skidding tire on dry pavement. This heat can be used to generate electricity, and it is precisely this technique that is used to power deep space probes. The vivid pictures returned to Earth from Mars during the *Viking* mission were made possible by radioactive heat sources. This is the technique utilized to power the *Voyager* "twins" and other space probes—a topic covered by Bennett (2021) in Chapter 4, Section 9 of this encyclopedia. Properly designed, such power sources can last for decades—without any moving parts (Fig. 2).

Pu-238 is often used as the alpha emitter to provide this heat source. This material is encased in a unit called a radioisotope heater unit (RHU). Pu-238 is not fissile, but it has a half-life of 87.5 years, allowing the RHU to safely provide 50% of its initial heat after 87.5 years of use. These units are productively employed in space probes and other spacecraft to keep them from freezing in the unforgiving environment far removed from the atmosphere of the earth. By utilizing the thermoelectric principal of attaching two insulated wires made of dissimilar materials (i.e., nickel and copper) and attaching one end to the heat source and the other end to a cooling junction that can reject heat to space, an electrical current can be generated. This unit is called a radioisotope thermoelectric generator (RTG). Fig. 3 is an illustration of a hot glowing pellet of Pu-238 encased in an RTG.

It may be of interest to the reader that it is the radioactive decay of uranium-238 ($T_{1/2} = 4.46$ billion years), thorium-232 ($T_{1/2} = 14$ billion years), and potassium-40 ($T_{1/2} = 1.27$ billion years) that provide the earth with its enormous heat source just below the surface of the globe.

Material Penetration

- Degree of beam attenuation determines thickness of material
- Metal foil and paper manufactured by this process

Fig. 1 Material penetration.

Heat Source

- Alpha and beta particles stop within short distances of their origins
- Substantial heat is generated in this process
- Heat can be used to generate electricity (e.g. thermoelectric effect)
- Such sources used in space probes (e.g. Viking mission to Mars)

Fig. 2 Heat source.

Fig. 3 A glowing Pu-238 pellet encased in an RTG. Source: Wikipedia.

Emission

Many isotopes emit gamma rays during the radioactive decay process, often in conjunction with other particle emissions. Since gamma rays can penetrate through a relatively large mass, it is possible to attach specialty gamma emitters to materials via chemical means that can easily be transported by fluids. Such a linkage allows the gamma-emitting radioisotopes to flow through a set of pipelines or blood vessels, thus allowing the location of this radioactive material to be measured as a function of time. This *tracer* or *labeling* technique is routinely used to map groundwater movement, detect pipe leaks in the petroleum industry, and diagnose ailments in the human body. As might be expected, this technique has made a powerful impact on the world of medicine (Venkatesh and Kang, 2021). It likewise is prolifically used in many aspects of both agriculture and modern industry (Sivasankar et al., 2021; Viljoen et al., 2020; Thereska and Brisset, 2021a) (Fig. 4).

Transmutation/activation

By focusing a beam of neutrons on unknown materials, it is possible to transmute (fundamentally change) the target material into another isotope (or possibly an isotope of a different element). If this new isotope is radioactive, it will emit a radiation signature that uniquely determines its identity. It is then a very simple process to identify the target material (the original unknown material) that was converted to the measured resulting product created by absorption of the neutron beam. This property is used routinely for

Particle Emission

- Gamma rays can penetrate through substantial material
- Hence, isotopes that emit gamma rays can be attached to fluid materials & then continuously monitored vs time
- Such tracing techniques are used to map groundwater movement, detect pipe leaks, & diagnose ailments in the human body

Fig. 4 Particle emission.

criminology investigations (Patton, 2021; Strellis and Gozani, 2021; Fedchenko, 2021). It is also useful in determining the impurity levels in materials (Bjornstad, 2021b,c) (Fig. 5).

Change chemical structure

Bombarding some materials with intense beams of gamma rays, electrons, or neutrons can break molecular bonds and evolve new types of materials (i.e., change the chemical or physical structure). Such treatment is used to produce stronger plastics or increase the rate of chemical reaction (Fulvio, 2021). This approach is even used to enrich the color and brilliance of some types of gemstones by slightly modifying their structure (Waltar, 2021) (Fig. 6).

Cell destruction

In a manner similar to the above, controlled amounts of beta particles, X-rays, or gamma rays can be used to kill microorganisms or sterilize unwanted insects. This property is used in millions of operations per year for sterilizing hospital equipment (Kalia, 2021), killing food pathogens (i.e., any microorganisms that can cause disease) and suppressing sprouting in vegetables, and eradicating cancer cells (Venkatesh and Kang, 2021). It is this property that allows for a potential transformation in our massive food industry—to provide safer produce with a longer shelf life (Pillai and Pillai, 2021) (Fig. 7).

Transmutation/Activation

- Neutrons focused on certain materials will transmute the target material into a new radioisotope
- The target material can then be identified by analyzing the radioactivity of the newly formed radionuclide
- This technique is often used in criminology investigations and for revealing explosives in airport luggage

Fig. 5 Transmutation/activation.

Change Molecular Structure

- Bombarding some materials with high enough levels of tailored radiation will break molecular bonds
- This changes the chemistry and structure of materials
- Sample products are tough plastics & special rubber for tires

Fig. 6 Change chemical structure.

Cell Destruction

- In a more macro scale, controlled amounts of beta particles or gamma rays can be used to break DNA bonds, thereby killing undesirable cells (e.g. insects & pathogens)
- This process is used to sterilize hospital equipment, suppress sprouting in vegetables, and kill cancer cells

Fig. 7 Cell destruction.

Decay time

Knowing the “half-lives” of certain radioactive isotopes (i.e., the time it takes for one-half of the atoms of a certain species to decay into another species), it is possible to perform aging analyses on a variety of archeological artifacts—including the age of Earth (Varquez and Nagai, 2021). This is the technique used to determine prehistorical climate changes, the role of the industrial age in contributing to greenhouse gases, and so on.

Carbon dating is the process that is the most familiar. Natural carbon (C-12) is stable, i.e., it does not decay. It constitutes 98.89% of all carbon in existence. However, carbon-13 also exists in nature (comprising essentially the remaining 1.11%). But of most interest to us within the present context is that carbon-14 also exists in nature as a result of cosmic radiation. Neutrons from outer space react with nitrogen in the upper atmosphere to form carbon-14 plus a proton. The amount of carbon-14 is exceptionally small. In fact, for every carbon-14 atom existing in nature, there are one trillion atoms of carbon-12.

Even though the amount of carbon-14 is exceedingly small, there exists a constant ratio of carbon-14 to carbon-12 naturally occurring in our environment at all times. All living beings (whether plant or animal) have this same ratio in their systems, since they all have a constant intake of carbon while still alive. But when such plants or animals die, there is no more intake of carbon in any form. Carbon-12 is stable, but carbon-14 decays with a half-life of 5715 years. Consequently, the ratio of carbon-14 to carbon-12 diminishes with time in dead species. This change in the ratio of carbon-14 to carbon-12 can then be used to determine the age of the dead matter.

Since the half-life of carbon-14 is 5715 years, there is a practical limit of time for which the standard carbon dating method is accurate. This is generally in the range of 50–50,000 years. However, it is now possible to directly detect individual carbon-14 atoms in a sample—one carbon-14 atom out of 10^{16} atoms of C-12. This allows a significant refinement in determining the age of the dead object.

Other radioactive techniques have been developed to measure artifacts up to several million years of age, based on the bombardment of cosmic rays that create radioisotopes of beryllium and aluminum. When an earth movement (such as a volcano, earthquake, or mud slide) buries sediments containing these metals, the cosmic ray bombardment stops. However, the radioactive isotopes continue to decay. Hence, the “clock” is set at this time. Beryllium-10 has a half-life of 1.5 million years, and aluminum-26 has a half-life of 0.71 million years. The age of the sediment specimen can be determined by measuring the change in the ratio of these two radioisotopes.

Many other applications utilizing the long half-lives of substances such as uranium and potassium have allowed accurate measurements to be made for the age of the earth, the effect of an asteroid hitting the earth some 65 million years ago, etc. More detail for the numerous applications of exploiting the property of radioactive decay is provided in (Varquez and Nagai, 2021) (Fig. 8).

Luminescence

Particles emitted from radioactive decay can cause the emission of visible light when interacting with certain target materials. Tritium emits beta particles as it decays and the beta radiation can excite a luminescence material upon impact to produce visible light. Tritium, mixed with a suitable luminescence material, is routinely used in the form of a “paint” for lighting airport runways (Waltar, 2021). It is likewise used for exit signs or other safety equipment in remote areas where it is not economical to deliver electricity or where 100% reliability must be guaranteed—even when all power is lost (Fig. 9).

Ionization

Radiation striking outer-shell electrons can, if sufficiently energetic, knock such electrons out of orbit and cause the targeted material to become ionized. This is called ionizing radiation. The targeted material then contains free radicals. When the striking radiation is very intense, it can enhance polymer chains to form useful products such as polyethylene, PVC pipes, and heat-shrink plastics. Conversely, it can also degrade polymers to make products such as Teflon and cellulose (Fulvio, 2021) (Fig. 10).

Decay Time

- Knowing the half-life of certain radioactive species, aging analyses are possible
 - Archeological artifacts
 - Age of the earth
 - Prehistoric climate changes
 - Industrial age climate stability

Fig. 8 Decay time.

Luminescence

- Some radioactive materials (e.g. tritium) can produce wave lengths in target materials that are visible to the human eye
- Routine uses include lighting for airport runways
- 100% reliable & self contained

Fig. 9 Luminescence.

Ionization

- Sufficiently high energy radiation will knock off electrons in surrounding media
- Media becomes electrically charged

Fig. 10 Ionization.

X-ray fluorescence

X-rays focused on a material of unknown composition can knock out inner electrons from the atomic structure of the unknown material. When this happens, electrons from the outer shells will refill the vacated site. The movement of these electrons causes the emission of X-rays with energies and relative intensities characteristic of each element comprising the unknown material—thus allowing precise identification of the unknown composition (Patton, 2021; Strellis and Gozani, 2021; Fedchenko, 2021). This is a powerful method for measuring concentrations of trace elements and is used in any fully equipped analytical laboratory. It is often employed for criminology work (Fig. 11).

Neutron slowing down

If a burst of energetic (fast) neutrons is introduced into a media, these neutrons will collide with the nuclei of surrounding atoms—thus losing energy and slowing down to velocities typical of ordinary materials (i.e., thermal speeds). This slowing-down process can take place very rapidly if there is a substantial water component in the surrounding media, since water contains hydrogen (an element consisting of a single proton). A fast neutron colliding with a proton can lose all of its energy in a single collision—in the same manner as a cue ball that is stopped in its tracks upon a “bull’s-eye” collision with the eight-ball. However, when a fast neutron collides with a heavier element, such as iron or lead, it loses its energy gradually and many collisions are required for the neutron to reach thermal speeds. This property can be used to obtain an accurate measurement of how much moisture is contained in a particular medium (such as soil), since the number of slow (thermal) neutrons detected is directly proportional to the number of water molecules in the immediate vicinity (Sivasankar et al., 2021).

This property is extensively used for prospecting good sites for oil wells (Thereska and Brisset, 2021b; Bjornstad, 2021b,c) and the discovery of other productive mineral sites (Fig. 12).

Neutron or photon scattering

As a variation to the neutron slowing-down property noted above, if a neutron colliding with a nucleus of unknown identity does not make a “bull’s-eye” hit, it will scatter forward or backward at some angle relative to its original direction. This information can be

X-Ray Fluorescence

- Monochromatic X-rays focused on a material of unknown composition
- Inner shell electron ejected
- Outer shell electrons move to inner shells, emitting an X-ray characteristic of unknown material

Fig. 11 X-ray fluorescence.

Neutron Slowing Down

- A burst of fast neutrons injected into a medium
- Neutrons will slow down rapidly if the medium is rich in protons (i.e. water)
- Excellent way to determine moisture content

Fig. 12 Neutron slowing down.

used to determine the identity of the unknown scattering material (Patton, 2021; Strellis and Gozani, 2021). Gamma or X-ray backscattering is a variation of the same theme (Bjornstad, 2021a). The difference between gamma or X-ray scattering and neutron scattering is that gamma and X-rays interact with the atomic electrons whereas the neutrons interact with the nuclei of the atoms. These techniques can be used to analyze materials on the surface of bulk matter, such as the thickness of plastic coatings on metals (Theriska and Brisset, 2021a). X-ray backscattering is routinely used in airports to screen passengers for hidden materials (Radiation and Airport Security, <https://www.epa.gov/radtown/radiation-and-airport-security-scanning#about-radiation>) (Fig. 13).

Fission

For certain heavy isotopes such as uranium-233, uranium-235, or plutonium-239, the absorption of even a low-energy ("thermal") neutron can cause a transformation to take place that produces a nucleus sufficiently unstable that it will literally break apart, generally resulting in the release of two fission fragments, several new neutrons, and an enormous amount of energy (~ 200 MeV per fission event). When the fission event takes place, the mass of the two fission fragments (or fission products) and associated free neutrons is slightly less than the mass of the original fissionable element and the neutron it absorbs, and this loss of mass is instantly converted into energy via the famous Einstein equation:

$$E = mc^2$$

Neutron or Gamma Scattering

- The identity of unknown material can sometimes be determined by measuring the scattering angle of a focused beam of incident neutrons or gamma rays

Fig. 13 Neutron or gamma scattering.

where E is energy, m is the mass lost, c is the speed of light.

The same equation can quantify the energy released in radioactive decay, such as the decay of Pu-238 described in the “Heat Source” section above. A nuclear reactor operating on the fission concept is designed so that a sufficient number of neutrons released during a fission event will cause subsequent fissions, resulting in a self-sustaining chain reaction. The fuel and absorber assemblies are arranged and controlled such that the number of fission events per unit time remains constant—producing a steady-state generation of power.

Fig. 14 is a very simplified illustration of a U-235 fission event, whereas Fig. 15 is expanded to illustrate the eventual production of Pu-239, which is another fissile isotope. The latter production is a result of a neutron capture in U-238 to form U-239, followed by a beta emission to form Np-239, and then followed by another beta emission to form Pu-239. The result is that a reactor initially fueled with only uranium ends up with fission occurring from both U-235 and Pu-239. After several months of operation, about a third of the power is generated by plutonium.

The heat generated by the fission process is transferred to a coolant that, in turn, converts its energy to a rotating turbine-generator system to produce large amounts of electricity. The bulk of this encyclopedia is dedicated to this topic.

Fusion

For very light isotopes, such as deuterium (a hydrogen atom containing a neutron in addition to a proton) or tritium (a hydrogen atom containing two neutrons in addition to a proton), it is possible that a collision of deuterium and tritium at high enough speeds (i.e., exceedingly high temperatures!) will cause the two nuclei to fuse and form a new isotope—yielding an energy release (in the case of a D-T reaction) of 17.6 MeV—via the same mass/energy equivalence equation noted in the previous section. This energy release is substantially greater than in the fission process outlined above if measured per unit mass of the reacting nuclei. This process is called nuclear fusion (Fig 16). The fusion of light isotopes is the energy source for our sun (primarily converting ^2H nuclei into He) and all the other stars.

The principal challenges of harnessing the nuclear fusion process for commercial use include the extremely high temperatures (~ 14 million degrees Kelvin) required to initiate the fusion process, and the difficulty in constraining this extremely hot plasma.

Fission

- Very heavy fissile isotopes (e.g. U-235, Pu-239) will likely undergo fission (i.e. break apart) upon absorbing a neutron
- The mass lost in the process is converted into energy
 $E = mc^2$ (energy = mass times the speed of light squared)
- Two fission fragments usually result, along with 2 or 3 neutrons to continue the chain reaction

Fig. 14 Highly simplified nuclear fission.

Fig. 15 ^{235}U fission process to produce the fission fragments ^{92}Rb and ^{140}Cs and eventually ^{239}Pu . Source: Wikipedia.

Fusion

- Very light isotopes (e.g. deuterium, tritium), if brought together at very high velocities (i.e. very high temperatures), will fuse together, forming a new element.
- The mass lost in the process is converted into an immense amount of energy
 $E = mc^2$ (energy = mass times the speed of light squared)

Fig. 16 Highly simplified nuclear fusion.

Fig. 17 The fusing of deuterium (^2H) and tritium (^3H) (Wikipedia).

However, the lure is very strong for ultimate success. Accordingly, progress to harness this process continues in many parts of the world (Fig. 17). The state-of-art in the pursuit of ways for harnessing nuclear fusion to the benefit of mankind is covered in detail in Section 12 (Nuclear Fusion R&D) of this encyclopedia.

Hopefully, this brief overview has helped take some of the mystery out of how nuclear radiation can be productively employed. Its many unique characteristics afford a plethora of opportunities for scientists and engineers to tap its power for beneficial use. Now that we have a better understanding of where to “strap the harness,” we can begin our investigation of the numerous ways that radiation has so effectively improved our lives.

Glossary

Absorbed dose The amount of energy absorbed per unit mass of irradiated matter,

$D = dE/dm$, where

D = Absorbed dose

dE = mean energy

dm = mass of matter

Beam energy The kinetic energy of the accelerated electrons in the beam. The beam energy determines the depth of penetration of electrons. Beam energy is measured in Electron volts (eV).

Beam spot profile The shape of the unscanned electron beam incident on the reference plane.

Bio burden The population level of viable microorganisms on or in raw materials, products, and labeling/packaging materials determined before sterilization.

Becquerel (Bq) The derived unit for radionuclide activity. One Becquerel equals one nuclear transformation per second. The unit 'Curie' was earlier used to indicate activity

$1 \text{ Curie} = 3.71 \times 10^{10} \text{ Bq}$

Conversely $1 \text{ Bq} = 2.7 \times 10^{-11} \text{ Curies}$

Typically, a commercial gamma irradiator will have a source strength of 1 million Curies ($3.71 \times 10^{16} \text{ Bq}$).

Calibration A set of operations that establish, under specified conditions, the relationship between values of a quantity indicated by a measuring instrument or measuring system, or values represented by a material measure or a reference material, and the corresponding values realized by standards.

D value A value indicating the extinction rate of microorganisms killed under defined conditions.

D_{10} value The time or radiation dose required to inactivate 90% of a population (only one tenth of the starting value remaining) of the test microorganism under stated exposure conditions.

Dose Limit Ratio (DLR) The ratio of the upper regulatory dose limit to the lower regulatory dose.

DNA Deoxyribonucleic acid; the information-carrying genetic material that comprises the genes. DNA is a macromolecule composed of a long chain of deoxy-ribonucleotides joined by phosphodiester linkages. Each deoxy-ribonucleotide contains a phosphate group, the five-carbon sugar 2-deoxyribose, and a nitrogen-containing base.

Dose Quantity of ionizing radiation energy imparted per unit mass of a specified material. The unit of absorbed dose is Gray (Gy), where 1 Gy is equivalent to the absorption of 1 J/kg.

Dosimeter A device having a reproducible, measurable response to radiation, which can be used to measure the absorbed dose in a given system.

Dose Uniformity Ratio (DUR) The ratio of the maximum dose absorbed by the product to the minimum dose absorbed by the product. In a gamma irradiator, this ratio increases with the density of the product as well as with the size of the container. This term is used as a measure of the dose distribution within a product that is irradiated. In an irradiation plant, a low DUR avoids unnecessary treatment, while a high DUR indicates better efficiency of energy utilization.

Dose Limit Ratio (DLR) The upper regulatory dose limit to the lower regulatory dose limit.

Electron accelerator A device that emits high energy electrons.

Enzyme A protein that accelerates a specific chemical reaction in a living system.

Electron volt (eV) A unit of energy. One electron volt is the kinetic energy acquired by an electron in passing through a potential difference of one volt in vacuum. $1 \text{ eV} = 1.60219 \times 10^{-19} \text{ J}$.

Pharmaceutical Formulation This is the process, in pharmaceuticals, in which different chemical substances, including the active drug, are combined to produce a final medicinal product.

Free radicals An uncharged molecule (typically highly reactive and short-lived) having an unpaired valency electron.

Gray (Gy) This is the SI unit for absorbed dose. Gray has replaced 'Rad,' which was earlier used to measure absorbed dose.

$$1 \text{ Gy} = 1 \text{ J/kg} = 100 \text{ Rad}$$

$$1 \text{ kGy} = 1000 \text{ Gy}$$

Inherent product bio burden The bio burden present on a product after its manufacturing process before the product is sterilized.

Installation Qualification The process of obtaining and documenting evidence that equipment has been provided and installed in accordance with its specification.

Ionization A process in which a charged particle is created from a parent atom or molecule or other bound state.

Isotope Nuclides having the same atomic number, Z (i.e. the same chemical element) but having a different mass number, A .

Irradiation Operator The company or body responsible for the irradiation of a product.

Maximal resistance Components identified as having high resistance, among the reference set of resistances of micro-organisms. This value helps in substantiating the dose as per the $VD_{\max}$ method.

Maximum acceptable dose The dose given in the process specification as the highest dose that can be applied to a defined product without compromising safety, quality or performance.

Molecular bond A molecular bond, usually a covalent bond, is a chemical bond that involves the sharing of electron pairs between atoms.

Operational Qualification A process of obtaining and documenting evidence that installed equipment operates, within predetermined limits, when used in accordance with its operational procedures.

Performance Qualification Process of obtaining and documenting evidence that the equipment, as installed and operated in accordance with operational procedures, consistently performs in accordance with predetermined criteria and, thereby, yields a product meeting its specification.

Poisson distribution A discrete probability distribution that expresses the probability of a given number of events occurring in a fixed interval of time or space if these events occur with a known constant mean rate and are independent of the time since the last event.

Practical electron range (r_p) The depth in homogeneous material to the point where the tangent at the steepest point (the inflection point) on the almost straight descending portion of the depth-dose distribution curve meets the extrapolated X-ray background (see Fig. 4).

Primary Manufacturer The body responsible for the design and manufacture of a medical device, together with the safety and performance of that medical device when placed on the market.

Process thickness A term usually used in relation to electron beam radiation. The process thickness is defined as the depth at which the dose equals the entrance (surface) dose. See "useful range" in Fig. 4.

Radiation resistance of a population The resistance shown by a population of micro-organisms to radiation. It is dependent on the amount of absorbed radiation energy required to inactivate the mixture of microorganisms present on a product. Radiation resistance, even under comparable conditions, varies widely among different microorganisms.

Radioisotopes The unstable form of an element that emits radiation to transform into a more stable form. Emitted radiation brings about a change on the product when exposed.

Of the 118 elements enlisted in the periodic table, only 94 radioisotopes occur naturally, and radiation emitted by them are of different types, most often alpha, beta and gamma.

Most radioisotopes used for industry are artificially produced in research reactors and accelerators by exposing a target material to 'intense particles,' such as neutrons or protons (neutron flux in a nuclear reactor), followed by different chemical processes to bring them into the required chemical form (Previtali, 2021).

Sterility Assurance Level (SAL) The probability of a single viable microorganism occurring on an item after sterilization.

Scan width The dimension of the irradiation zone perpendicular to the direction of product movement at a specified distance from the accelerator window.

Standard distribution of resistances (SDR) A reference set of resistances of microorganisms and corresponding probabilities of occurrence.

Sterilization A validated process used to render a product free from viable microorganisms.

Sterilization dose The minimum dose to achieve the specified requirements for sterility.

Terminal sterilization A process whereby a product is sterilized in its final container or packaging, which permits the measurement and evaluation of quantifiable microbial lethality. It is an important process, as it ensures the product remains sterile.

Uncertainty of measurement A parameter associated with the result of a measurement that characterizes the dispersion of values that could reasonably be attributed to the measurement

VD_{max}¹⁵ The maximal verification dose for a given bioburden, consistent with the attainment of an SAL of 10^{-6} at a specified sterilization dose of 15 kGy.

VD_{max}²⁵ The maximal verification dose for a given bioburden, consistent with the attainment of an SAL of 10^{-6} at a specified sterilization dose of 25 kGy.

Introduction

The word ‘sterilization’ brings to mind terms like pure, clean, aseptic, safe, hygienic and hospitals, hospital equipment and, rightly so, as it is associated with medicine, medical devices, etc., key for an under-treatment patient’s recovery in a hospital, or even otherwise.

We address the seven questions i.e., Why, How, How Much, What, Where, When and Who related to sterilization of medicines using irradiation.

Why

Comparatively, medical practices were relatively unhealthy until the late 1800s, and once the germ theory of diseases gained credibility, practitioners understood the cause for increased cases of disease in a hospital environment. Antiseptic surgical dressings, importance of disinfection and sterilization processes, were introduced towards the end of the 19th century. For example, Ernst von Bergmann introduced the autoclave in the 1870s, a device for sterilizing surgical instruments. A few decades later, in the 1920s, wide-scale production of syringes and needles began. Since these early beginnings, hygienic practices and sterilization continued to evolve and have helped control the spread of disease and infections. The first use of Ethylene oxide gas as a hospital sterilant occurred in 1940, radiation sterilization was introduced in 1956 and, in particular, gamma radiation sterilization in 1964 facilitated industrial scale sterilization.

A sterilization process renders products free from viable micro-organisms such as bacteria, fungi and their spore forms and viruses.

Sterilization is an important stage in the field of medicine and healthcare. Its application starts right from the medicine that is administered to a patient and to various accessories, devices, instruments and equipment used for treating a patient. While medicines such as peptides, proteins and some chemotherapeutic agents, when ingested, are naturally sterilized in the patient’s gastrointestinal tract, medicines that are administered through intravenous/intramuscular injections are required to be necessarily sterilized to prevent complications, even mortality.

In addition to medicines, various components in the chain also need to be sterile, whether these consist of large equipment, packaging components, pre-assembled kits, etc.

How

a. Radiation effect on micro-organisms

The binding energy of molecular bonds is known to be below 12 eV (eV). During the radiation process, an energy level of 10 eV or more is deposited onto the micro-organisms, which leads to a chemical reaction and breakage of molecular bonds—leading to inactivation of micro-organisms. This inactivation takes place either due to direct energy deposition (ionization) on vital components of the micro-organisms, or indirectly due to formation of highly reactive chemical radicals that, in turn, bring about random detrimental reactions in the micro-organism.

Targets for direct ionization could be the DNA molecule, or an enzyme, or any other crucial molecule in the cell causing significant change in the cell. Such multiple changes will result in complete inactivation of the cell. Damage to the cell membrane structure or cell respiratory functions are some examples of changes that result in complete inactivation of micro-organisms.

Fig. 1 Example of direct and indirect effect of radiation resulting in cell damage.

All micro-organisms have a certain amount of water. Radiation causes formation of free radicals (OH^* and H^*) and molecules such as H_2O_2 , from water, which are highly reactive and react with the vital components of micro-organisms. These reactions are lethal and, thus, indirectly cause inactivation of micro-organisms (Fig. 1).

b. Concept of SAL

Inactivation or sterilization of micro-organisms by irradiation follows an exponential law, i.e., no matter how high the irradiation dose is, there is always a chance that a micro-organism has survived the process. Thus, evidence that a product is sterile is proved only in terms of probability. Sterility of a product is defined in terms of the probability of existence of an unsterile product in a population, and the term used to indicate this probability is Sterility Assurance Level (SAL). SAL is a function of the number and types of micro-organisms on the product, the lethality of the sterilization process, and sometimes the environment in which micro-organisms exist during treatment.

Each log reduction—a reduction by a factor of 10—represents 90% reduction in micro-organism population. Thus, a 6-log reduction indicates that the microbial population has reduced by a million, which is theoretically close to zero. SAL is normally expressed as 10^{-n} . Some countries mandate a maximum SAL of 10^{-6} in sterile medical devices. Different values of SAL may also be selected; however, these matters are usually regulated by national licensing bodies.

How much

It is essential to first determine the maximum acceptable radiation dose that a product could withstand without affecting its intended functions. Next, the sterilization dose at which the product is rendered sterile is determined. The sterilization dose identified should be less than, or equal to, the maximum dose determined—failing which, the product cannot be sterilized by irradiation.

As mentioned above, a SAL of 10^{-6} is accepted by most countries, although it begs the question as to what is the optimal dose of irradiation required to achieve a SAL of 10^{-6} . This dose is product-specific and depends on the bio burden, D_{10} values and the SAL required.

The sterilization dose may be determined using any of the three methods, i.e., Method 1, Method 2 or VD_{max} method. The Product performance qualification mentioned earlier is conducted using the sterilization dose thus determined.

Approaches to determine the Sterilization Dose.

- Method 1:** In this method, the radiation resistance of the inherent product bio burden is compared with the radiation resistance of a population (mixture of micro-organisms) having a standard distribution of resistances (SDR).

The various doses to achieve a SAL of 10^{-2} , 10^{-3} , 10^{-4} , 10^{-5} and 10^{-6} , for increasing levels of an average bio burden, of a microbial population having SDR, are arrived at using computational methods (Tables 5 and 6 in ISO 11137 – 2).

Once the average bio burden in the product is determined, the dose required to achieve a SAL of 10^{-2} in the SDR population is arrived at referring to Tables 5 and 6 of the above Standard. One hundred units of the product are subjected to this dose and individual sterility tests are conducted on these 100 units. If ≤ 2 positive sterility tests are determined in these 100 product units, it verifies that the product bio burden is more sensitive than the SDR population and, thus, the dose for the desired SAL is arrived at, for routine processing, after referring to Tables 5 and 6. The rationale for allowing 2 positive sterility tests is arrived at by applying the Poisson distribution, which indicates that there is a 92% probability that 0, 1 or 2 positive tests will occur.

- Method 2:** The sterilization dose in this Method is also arrived at by using the radiation resistance of the product bio burden. Incremental doses are subjected to 100 product samples. Of these incremental doses, the dose at which ≤ 2 positive sterility tests are achieved will be the dose at which a SAL of 10^{-2} is achieved. Based on this finding, the dose for SAL values below 10^{-2} is extrapolated and determined. The validity of the extrapolation is confirmed using computer simulations.

- VD_{max}^{25} method or VD_{max}^{15} method:** In this method, the dose of 25 kGy* or 15 kGy is selected. It is further substantiated that this dose ensures sterility to the product. The rationale, however, is similar to the one used for Method 1. The radiation resistance of a population with maximal resistance is then determined and the doses to achieve various SAL for such a population is tabulated in Tables 9 and 10 of the standard ISO 11137-2. The average product bio burden is thereby determined. The dose (VD_{max}^{25} or VD_{max}^{15}) required for a SAL of 10^{-1} in a population with maximal resistance is identified and 10 units of the product are subjected

to this $VD_{\max}^{25}$ or $VD_{\max}^{15}$ dose. If there is $\leq$ one positive sterility test from these 10 irradiated product units, then the dose of 25 kGy or 15 kGy stands substantiated.

*Historically, 25 kGy was identified to achieve a SAL of 10^{-6} . Thus, this was the preferred dose by most primary manufacturers. However, with the introduction of the standard ISO 11137 in the year 2006, doses lower than 25 kGy have been identified and permitted to provide a SAL of 10^{-6} .

What

Methods of sterilization

The established methods of sterilization are:

- o High temperature/pressure sterilization (by dry heat or moist heat)
- o Chemical sterilization (e.g. Ethylene oxide gas)
- o Filtration
- o Radiation sterilization (Gamma/Electron beam)

In selecting the sterilization process, due weightage should be given to ensure product quality is maintained. The method of choice should not affect polymers, seal strength, label and box adhesion, corrugated and paperboard strength, and also the product's color. Radiation sterilization, being a cold process, helps address these issues more effectively compared to others. Furthermore, this facilitates sterilization of pre-packed, ready-to-use products without any quarantine restrictions.

The method covered in this chapter is about Radiation sterilization using:

- o Radioactive gamma sources and
- o Electron beam accelerators

In both cases, ionizing radiation facilitates sterilization. Described below are some aspects of such facilities.

Irradiation facilities using radioactive gamma sources

Two radioisotope sources can be used in irradiation facilities; namely Cobalt – 60 (^{60}Co) and Cesium – 137 (^{137}Cs). Of these, ^{60}Co is commercially more popular as it can be conveniently produced from nuclear reactors in a large quantity. Typically, a ^{60}Co pencil can be used for about 20 years in an irradiator. (Pencils containing slugs or pellets of ^{60}Co are prepared by irradiating 99.9% pure sintered Cobalt powder in Zirconium alloy capsules in a nuclear reactor for about 18–24 months, during which ^{59}Co is converted to ^{60}Co). Periodical replenishment of the source is necessary to compensate for the decay of the radioactive source material (the half-life of Cobalt-60 is ~ 5.28 years).

Various types of commercial irradiators can be designed. The irradiators mainly have two variables; namely, the activity level of radiation source and the product movement around the source for uniform absorption of radiation. The activity level (capacity) of the radiation source may vary from a few thousand Curies to several million Curies. The installed capacity of a facility is always less than or equal to the designed capacity. The dose that a product receives depends on the installed source activity and the residence time in the irradiator. The dose is controlled by adjusting the time that the product is exposed to the source, i.e., time in an irradiation cell, which depends upon the conveyor speed (the product moves around the source). The irradiation time needs a periodic adjustment, which depends on the source strength, since the source decays as a function of time.

It is prudent to design irradiators to maximize energy utilization and dose uniformity in products. This generally poses a challenge due to the wide range of products to be irradiated.

There are two types of Irradiator designs popularly used by the trade:

1. *The Product overlap* design—where two rows of stacked metal containers (placed one above the other) known as totes are used, which move in four/six paths around the source (two/three on either side). A tote is versatile to be able to accommodate bags, cartons or drums. The combined height of the two totes, stacked one above the other, is greater than the height of the source rack, and thus the term 'Product overlap.' Shuffling of the totes is essential to ensure dose uniformity in the product. Since most of the radiation emitted by the source is intercepted by the tote arrangement (and, therefore, absorbed by the product), energy utilization is high in such facilities. It is important to align the center of the product stacks to the center of the source rack to achieve optimum dose uniformity.

An example of a product overlap design is the pallet irradiator where a loaded pallet moves around the source, which helps save time as one can irradiate the packed pallet as a whole in its final form (Fig. 2A).

2. The second design is the *Source Overlap* design, where the height of the product carrier is shorter than the height of the source rack. Though energy utilization is lower, the product conveying systems are less complex, with comparable dose uniformity (Fig. 2B).

Fig. 3 provides an isometric view of a Product overlap Gamma irradiator.

Fig. 2 Diagrammatic representation of Source Overlap and Product Overlap Irradiator design.

Fig. 3 Diagrammatic representation of a Batch Irradiator.

Irradiation facilities using Electron beam (EB) accelerators

Electron beam accelerators produce intense high energy electron beams (up to 10 MeV), enabling such irradiation facilities, the advantage of processing higher throughputs compared to gamma sources. Energy utilization in such facilities is also higher as the beam is directed onto the product and energy wastage is minimum, as the EB facility can be switched ON or OFF depending upon the treatment requirements.

These accelerators are broadly classified, based on the energy range: Low, Medium and High energy accelerators of which medium (4–5 MeV) or high energy (up to 10 MeV) are ideal for sterilizing packed products. In EB irradiators, optimal utilization is achieved if the products are uniformly packed.

Industrial accelerators could either be Direct Transformer Accelerators operating in DC mode (ELV, Dynamitron, Cockroft-walton etc.), or RF based single resonant cavity accelerators (ILU type), or Linear accelerators (linacs) operating in pulse mode (IAEA, 2008). The accelerators today are designed to operate on 24 × 7 basis with minimal manual intervention and maintenance.

Product packs (cartons, etc.) are conveyed below the beam window where the scanned electron beam is made to impinge on the product. The energy absorbed by the product per unit mass varies, based on the extent to which the atoms (of product) scatter the electrons (from the beam) in all directions. The electrons gradually slow down after each scattering, and this slowing down increases the energy absorption efficiency by the product.

A typical depth dose profile within a product is shown below (Fig. 4).

From the figure, it can be observed that the dose is minimum at the surface, which progressively increases (with increasing thickness of the product) due to scattering that happens within the product. The dose peaks at a particular product thickness referred to as D_{max} , and subsequently the dose decreases with increasing product width. The dose at the surface of the product is known as the entrance dose. The depth within the product that equals the entrance dose is called the useful range, which is the effective thickness of the product that electron beam can bring about the desired sterilization/change in the product, with minimal DUR (Dose Uniformity Ratio).

The D_{min} position is usually at the surface of the product. The above (Fig. 4) one-sided radiation profile is for water. However, for products having lower density, the useful range would increase whereas the Dose Uniformity ratio (DUR) would decrease. The inverse happens for products with higher density i.e. the useful range decreases but DUR increases. From the profile, it can be

Fig. 4 Depth dose profile for 10 MeV electron beam.

inferred that the useful range for a unit product density is 4 cm thickness and the DUR i.e. $D_{\max}/D_{\min} = 130/100 = 1.3$. In order to increase the process thickness (the useful range), the product needs to be exposed from both sides. The depth dose profile for a 2-sided irradiation is shown in **Fig. 5**. The treatment efficiency is improved since all the energy is deposited within the product.

Upon exposure to electron beams from both sides for a product pack, the minimum dose received would be at the surface—as well as the point where the curves from both sides intersect. As shown in **Fig. 5**, if the product pack thickness for one-sided irradiation is 'x', then for double – sided irradiation the thickness of the subject product pack would exceed twice as much.

Electron penetration is proportional to its energy and inversely proportional to the product density, which is represented in the basic formula (for electron energies greater than 1 MeV):

$$\text{Penetration (cm)} = (0.524 E - 0.1337) / \rho$$

where E = Beam energy in MeV, ρ = density of product in g/cm^3 .

During routine operations of the EB irradiator, two parameters are essential for delivering a desired dose; namely, beam energy and current. The beam energy determines the maximum thickness of a product that can be effectively penetrated, whereas the current helps regulate the dose rate and, thus, the time of irradiation at which the product is irradiated.

The following gives the relation between the process thickness, d (in cm) and energy for 1-sided irradiation:

$$E = 2.63 d \rho + 0.32 \text{ (for 1-sided irradiation)}$$

However, as explained earlier, 2-sided irradiation would help in slightly more than doubling the product thickness that can be subjected to a particular dose with a known DUR as follows:

$$E = 1.19 d \rho + 0.32 \text{ (for 2-sided irradiation)}$$

A typical layout of an EB accelerator with various equipment is shown in **Fig. 6**.

Conveyor.

Commissioning (installation qualification and operational qualification)

In order to deliver a particular dose repeatedly, the operating conditions need to be set at the time of installation of an irradiator. This is achieved during commissioning studies where dose-distribution, throughput and reproducibility of absorbed dose for a homogenous material in a typical range of density, is related to operating parameters.

Installation qualification establishes that the entire equipment and its associated processing and measuring instruments are installed as per specification, whereas Operational Qualification establishes that the installed irradiator can operate within specified limits.

Most commercial irradiation facilities involve movement of product carriers around the source. Due to this, some positions in the product carrier would absorb maximum dose and some, the minimum dose. In order to locate these positions in the product carrier, extensive dose mapping is carried out.

Gamma irradiators

In a commercial gamma irradiator, these studies involve 3 sets of trials; namely, 'X' run, 'Y' run, and 'Z' run.

The 'X' run helps determine the alignment of the source rack with respect to product, the dose received at the center of product carrier, and the cycle time for the run (Fig. 7).

Fig. 7 Placement of dosimeters in X-Set at C-8 position.

The 'Y' run helps determine location of minimum and maximum dose inside product carrier. A considerable number of dosimeters (around 10–50 dosimeters) are placed in a systemic 3-dimensional form within the product carrier, with homogenous reference material, and irradiated for the cycle time determined in the 'X' run (Fig. 8).

The 'Z' run provides a statistical evaluation of the minimum and maximum dose positions and proves repeatability of dose distribution throughout the irradiator (Fig. 9).

Parameters like source strength, source arrangement, conveyor speed, dwell time, multi-pass mode, and irradiation geometry and bulk density of product are to be characterized for its complete range before commercial operations commence in an irradiator.

During gamma irradiation, gamma rays imparts energy (i.e. radiation dose) through atomic interactions such as photoelectric effect, Compton scattering (more predominant) and pair production (Maruyama, 2021). Due to these interactions, the intensity of the gamma rays decreases as they travel through the product. To attain a uniform dose in the product, the product container is rotated 180° during irradiation. The depth-dose distribution during one-side and two-side pass, around the source rack, is depicted in Fig. 10. The one-sided pass around the source results in a decrease in absorbed dose with increased product depth. However, the total dose due to irradiation from both sides is indicated by the curve 'a + b'. The dose achieved in the product by 2-sided irradiation is more uniform than by single side radiation processing (Fig. 10).

EB irradiators

The Operational Qualification of an electron beam irradiator facility involves characterization of parameters such as the mean energy of the electron beam, beam spot profile and scan width (Fig. 11). The energy of the electron beam is determined by the

Fig. 8 Placement of dosimeters in Y-Set at 1–15 position in planes A - E.

Fig. 9 Placement of dosimeters in Z-Set at A – 8 and C -8 positions, which are the maximum and minimum dose positions respectively.

Fig. 10 Dose distribution in a two - pass gamma radiation facility. Maximum and Minimum dose positions in a rectangular product that is irradiated and its cumulative dose distribution curve.

Fig. 11 Dose distribution along the Scan and Lateral direction of an electron beam irradiator.

depth-dose distribution study, which is conducted along the beam axis, with reference material that is generally polystyrene, water, graphite or aluminum.

The mean electron beam energy ($\bar{E}_0$) and the most probable beam energy (E_p) are determined using the formula

$$E_0 \text{ (MeV)} = 2.33 \times R_{50}$$

$$E_p \text{ (MeV)} = 0.22 + 1.98 R_p + 0.0025 R_p$$

where R_{50} is the depth at which the dose becomes half its maximum, expressed in cm in water; R_p is the practical range expressed in cm in water.

Dosimetry system

A dosimetry system helps in determining the absorbed dose. The dosimetry system consists of

- Dosimeter: This is any material wherein irradiation brings about a change that is measurable and repeatable.
- A measuring instrument: An instrument that measures the change in a dosimeter post irradiation.
- Procedure for analysis: A manual calculation of absorbed dose may result in errors. Thus, suitable software is available for computation and analysis of absorbed dose.

Based on intrinsic accuracy and application, dosimeters are classified into Primary, Reference, Transfer or Routine dosimeters. Various aspects of the dosimetry system are given in [Table 1](#) below.

Most gamma irradiators use alanine or ceric-cerous dosimeters for routine process monitoring, whereas thin film dosimeters are the preferred dosimeters in Electron beam irradiation facilities for routine process control ([Eckerman, 2021](#)).

Table 1 Classification of dosimetry systems.

<i>Class and salient features</i>	<i>Calibration</i>	<i>Uncertainty</i>	<i>Examples</i>
Primary • Absolute dose determination with reference only to SI units • Generally maintained by national standard laboratories	Not required	1%	Calorimeter, ionization chamber
Reference • High metrological quality • Effect of parameters need to be characterized	Required	1–2%	Calorimeter, alanine, dichromate, ceric-cerous, Fricke
Transfer • Used to transfer dose information from accredited calibration laboratory to irradiation facility • Generally reference standard dosimeters	Required	1–2%	Alanine, dichromate, ceric-cerous, Fricke
Routine • Used for dose mapping and routine dose monitoring • Shows variation from one manufacturing batch to another	Required	3–5%	PMMA, radiochromic and cellulose triacetate (CTA) films, ceric-cerous, ethanol-chlorobenzene (ECB)

Performance qualification

During Performance Qualification, values for various process parameters (operational as well as product and its packaging) are characterized. These parameters consistently provide sterile product with a high degree of confidence. Performance Qualification involves Dose mapping with actual product.

The position in at least one container in each irradiation path receiving the maximum and minimum dose is identified during Performance Qualification. The product, its packaging and its loading configuration in the irradiation container, is specified during the Performance Qualification studies and the same is to be followed during routine processing.

Depending on product homogeneity, a considerable number of dosimeters are labeled and affixed in an irradiation container. After irradiation, these dosimeters are carefully removed and the dose received is analyzed. The positions with maximum and minimum doses are identified, as well as the DUR. Ideally, the DUR calculated should be lower than the DLR. If it is vice versa, then process parameters would have to be adjusted in order to comply with this criterion, which is a pre-requisite for routine processing.

In some cases, the minimum dose could be in the center of the irradiation container. Hence, placing dosimeters for routine monitoring would require tampering with product packing. In such situations, a reference point at the surface is identified. The co-relation between this reference point and the minimum point is to be determined during Performance Qualification studies. The absorbed dose at both these positions should be reproducible.

During the Performance Qualification exercise, the exposure time requirement and processing rates are also determined.

This exercise is to be repeated whenever there is a change in source configuration/replenishment.

Routine sterilization and its control

After the Performance qualification studies are completed, the process parameters that a product category is to be subjected for sterilization is determined. Once the product is received for treatment, the incoming documents are reviewed for correctness with respect to count and product damage. Discrepancies, if any, are to be resolved before further processing of the consignment. Upon receipt, the consignment is stored in a designated area for Unprocessed Material with appropriate labels. These labels should contain details like the product name, consignment size, product lot number, etc. These labels may also be affixed with 'Go – No go' chemical indicators, which would help identify the stage of processing.

During processing, dosimeters are to be placed at positions identified as minimum dose and maximum dose identified during Performance Qualification studies. If the minimum dose position is inaccessible, the dosimeter is to be placed at the reference position, which is also identified during Performance Qualification studies. Loading of product into irradiation containers should be the same as done during Performance Qualification studies.

Irradiation of the product is closely monitored for the dose, exposure time in the radiation field, the source activity, product loading pattern and bulk density and distribution of product within the irradiator. Dosimeters placed within the product are retrieved carefully and analyzed for absorbed dose, post-irradiation.

At post treatment, the consignment is placed in the area demarcated for storage of processed products. The products received for treatment should follow unidirectional flow from Unprocessed to In-process to Processed storage areas. The products are then dispatched after review of processing records by authorized personnel.

Recent developments

The universally accepted SAL of 10^{-6} originated from the food canning industry, which was further adopted by the aerospace industry and the healthcare industry. A recent thought process that is emanating among researchers is challenging the requirement

of such a high SAL. Probabilistic models have been analyzed that suggest a lower SAL of $10^{-5}/10^{-4}/10^{-3}$ or for that matter even 10^{-2} may suffice for terminal sterilization of a medical device—especially those that have been aseptically manufactured.

Where

Irradiation facilities are designed and constructed after considering various factors at a site approved by the Regulators. The load bearing capacity of soil is an important factor, since the facilities are comprised of heavy concrete structures essential for biological shielding for personnel safety.

When

For pre-packed medical products, terminal sterilization radiation processing is the method of choice due to its inherent advantages, i.e., processing at ambient temperatures and adequate penetration.

Who

In the irradiation industry, two bodies are identified; namely, the primary manufacturer and the irradiation operator.

The *primary manufacturer* is the body who shall be responsible for the design and manufacture of the medicine, i.e. medical device or drug. They are also responsible for the safety of the medicine and to ensure its performance when it is placed in the market. Apart from controlling the medical devices manufacturing process (specifications like product density, orientation, dimensions etc.), the primary manufacturer is also responsible to develop product families, establish the maximum acceptable dose for the various product families, establish their sterilization dose, product performance qualification and product release into the market.

The *irradiation operator* is responsible for irradiation of the product. Their responsibilities are limited to the Installation Qualification, Operational Qualification, controlling the irradiation process, certification of the radiation dose subjected to the product, develop processing categories, and controlling changes to the irradiator.

Glossary

Alpha particles Alpha (α) particle or alpha rays, are particles with two protons and two neutrons, identical to a helium-4 nucleus, with an overall charge of +2. It is represented as ${}^4\text{He}^{+2}$.

Beta particles Beta (β) rays or beta particles are a type of particulate radiation with the mass of an electron emitted by certain radioactive nuclides. There are two kinds of beta rays. β^- rays have a charge of -1 and are identical with electrons. They are also known as negatrons. β^+ rays have a charge of $+1$ and are identical with positrons, which is the anti-matter of electron. Generally, the term “beta rays” is used to refer to β^- rays (negatrons) and β^+ rays are referred to as positrons. β^+ particle when emitted, travels until it encounters an electron and they get annihilated, their mass emitted as two photons of 511 keV (equivalent to the mass of an electron in accordance with $E=mc^2$) each at opposite (at 180 degrees) directions.

Computed Tomography (CT) Tomography is a three-dimensional image of a structure. When a series of plane cross-sectional images are used to construct a tomographic image using a computer to process the data, it is known as Computed Tomography or CT. In medical imaging field, X-rays are used for imaging to construct CT scans. As the CT image gives precise anatomical information, a combination of NM imaging and CT image is used for accurate diagnostic imaging.

Decay constant (λ) The decay constant of a radionuclide is the probability of the radioactive decay of a radionuclide. If there are N atoms of a radionuclide, then the number of nuclei that will undergo decay per unit time is $N\lambda$. This number is also

*Retired.

referred to as the “activity.” The larger the λ , the larger the activity per unit mass (also known as specific activity), and shorter is the half-life $T_{1/2} = 0.693/\lambda$.

Diagnostic nuclear medicine The branch of nuclear medicine used for diagnostic purposes.

Dosimetry Calculation of the radiation dose delivered to the target tissue and the various vital.

Electron capture-EC Electron capture is a mode of transmutation wherein a neutron deficient nucleus of a radionuclide captures an electron from one of the orbiting electrons, resulting in conversion of a proton into a neutron along with the emission of a neutrino (to balance the momentum). The transmuted/transformed nuclide has the same number of nucleons (mass number A) but atomic number (Z) less by one.

^{18}F FDG [^{18}F]-2-Fluoro-2-deoxyglucose, a radioactive compound used extensively in PET procedures.

Gamma rays Gamma (γ) rays are photons and are electromagnetic radiation. They have no charge or mass and are emitted from the nucleus of an atom when the atom undergoes transmutation. Emission of gamma rays does not change the atomic number or the mass number of the nuclide. The change is only in the energy levels within the nucleus.

Half-life The half-life of a radionuclide, denoted as $T_{1/2}$, is the time taken for one-half of the nuclei to decay (transmute spontaneously into the daughter nuclide by emission of radiation). The half-life depends on (and inversely proportional to) the probability of transmutation, which is also denoted as the “decay constant” represented as λ ; the larger the λ , the shorter the $T_{1/2}$. ($T_{1/2} \propto 1/\lambda$ and $T_{1/2} = 0.693/\lambda$).

Isotope Isotopes are atoms of the same element (same atomic number or number of protons(Z) in the nucleus), differing in the numbers of neutrons and hence different mass numbers(A). An atom is represented as ^A_ZX where X is the symbol of the element. However, since each element has a unique fixed “Z,” often the isotopes/radionuclides are expressed as ^AX . In this article, the radionuclides are expressed as ^AX or X-A or the full form of element name followed by its mass number. Example: Technetium-99m is represented either as Tc-99m or $^{99\text{m}}\text{Tc}$; Iodine-131 is represented either as I-131 or ^{131}I .

In Vitro In glass or outside the body.

In Vivo Inside the body.

LET Linear energy transfer—This term is used to indicate the capacity of a particulate radiation (such as alpha or beta rays) to transfer their energy into the matter they travel. Particulate radiations lose their energy upon interaction with atoms in their path of movement.

Molecular imaging This term defines an imaging modality in which the signal for imaging arises because of bio-molecular action/path of the tracer/probe used. Nuclear medicine imaging, wherein the radiopharmaceutical tracer acts at molecular level to provide information of bio-chemical action inside the body, is the most used “molecular imaging” modality.

Monoclonal antibodies-MAB These are antibodies that are derived from the same “clone” or a single antibody producing cell that has been multiplied, having identical characteristics and behavior.

Positrons Beta particles with +1 charge. See above the note on Beta particles for details.

Radioactive decay The process of transmutation/transformation of the nuclide of the radioisotope to a more stable isotope with emission of radiation (such as α , β , γ , X radiations or electrons). The radioisotope is referred to as the “parent” and the resulting nuclide after the transmutation is referred to as the “daughter.” When the parent nuclide transmutes from a higher nuclear state (metastable state) to the ground state of the same isotope, the decay is referred to as “Internal Transfer” (IT). The parent nuclide is denoted as $^A\text{mX}_Z$ and the daughter nuclide as $^A\text{X}_Z$ or $^A\text{gX}_Z$, wherein “m” indicates metastable state and “g” the ground state. Example: Technetium-99m ($^{99\text{m}}\text{Tc}$) decaying by IT to $^{99\text{g}}\text{Tc}$ (generally represented as ^{99}Tc).

Radionuclide An isotope of an element, the nucleus of which is unstable and transmutes (transforms; decays) into a more stable nucleus by either emission of one or more kind of radiations (α , β^- , β^+ , γ) or by electron capture.

Radiopharmaceuticals A drug formulation containing radioactivity, used in nuclear medicine for diagnostic imaging or therapy.

RBC Red Blood Corpuscles or Red blood cells are also known as erythrocytes and carry oxygen throughout the body.

RID RadioImmuno Diagnosis; a nuclear medicine procedure wherein a radiolabeled antibody (generally monoclonal antibody) is used for diagnostic purpose.

RIT RadioImmuno Therapy; a nuclear medicine procedure wherein a radiolabeled antibody (generally monoclonal antibody) is used for therapeutic purpose.

Therapeutic nuclear medicine The branch of nuclear medicine in which radiopharmaceuticals are labeled with radionuclides with therapeutic potential (high linear energy transfer).

Abbreviations

PRRT Peptide receptor radionuclide therapy

PET Positron emission tomography

SPECT Single Photon Emission Computed Tomography

Introduction

Nuclear Medicine (NM) is a specialty in which a radiolabeled molecule known as a “Radiopharmaceutical” is used for the management of diseases, either through diagnosis or treatment or monitoring treatment progress. Historically, radionuclides were used for the treatment of diseases soon after the radioisotopes were available, with radium being used to treat tuberculosis lesions as early as 1901. Several brilliant inventions and innovative ideas laid the foundation for the use of radioisotopes in medicine (SNMMI, 2020; EANM Publications-Tech Guide, 2019).

In brief, the invention of the cyclotron (Ernest Lawrence, 1930), the artificial production of radioisotopes (Irene Joliot Curie and Frederick Joliot, 1934), the concept of using radioisotopes as tracer inside a living being (Georg de Hevesy, 1935), and the achievement of controlled nuclear fission that formed the basis of nuclear reactors (Enrico Fermi, 1942), could be considered as the major factors that accelerated the growth of nuclear medicine. Radioisotopes produced using cyclotrons and nuclear reactors were explored for use in medicine, both for diagnosis and for therapy. Among the radioisotopes explored and used initially, Iodine-131 used in the treatment of thyroid cancers is an outstanding example, which continues to be used to this date (Fahey et al., 2017). With the growth in the nuclear industry and establishment of nuclear reactors and cyclotrons, which produce radioisotopes, the use of radioisotopes in nuclear medicine grew and expanded rapidly both in volume and variety. The advances in related fields such as molecular biology, immunology, cancer biology, radiolabeling techniques, automation, radiation detectors, computation, etc. aided significantly in the growth of nuclear medicine.

While nuclear medicine involves the ‘in-vivo’ administration of radiolabeled molecules, “in-vitro” use of radiolabeled molecules played a crucial role during 1970s and 80s. Rosalyn Yalow won a Nobel Prize in 1977 for discovering *Radioimmunoassay* (RIA), a system using radioisotopes for measuring minute quantities of hormones and biomolecules in human samples, like serum, with high sensitivity and specificity. This revolutionized the practice of endocrinology and oncology (Yalow Rosalyn, 1973).

A related procedure known as “Immunoradiometric assays” (IRMA), with higher specificity, were developed in later years. RIA and IRMA grew rapidly in the following decades and the availability of monoclonal antibodies gave a boost to development of such assays. “RIA/IRMA kits” that could be used in pathology labs for measuring nearly all the important hormones and several cancer antigens were developed. Iodine-125 is the most used radionuclide in these “in vitro” tests. While RIA/IRMA kits are still used for measurement of a few hormones in a few countries, most of these assays have shifted to the use of other tracers such as enzymes or fluorescent markers. The longer shelf-life of enzyme or fluorescent labeled biomolecules in comparison with radiolabeled molecules and the possibility to automate enzyme/fluorescent assays to have huge throughput are the reasons for the shift away from radiometric assays in pathology labs. However, radiometric assays are deemed to be the gold standard and are still developed and used to measure biomolecules in research (such as in new drug development).

Nuclear medicine has steadily grown over the past decades (Anderson et al., 2019; Ramamoorthy, 2020). Diagnostic nuclear medicine is predominantly used in oncology, cardiology, neurology, and functional imaging of many of the human systems. It is noteworthy that the World Health Organization (WHO) survey in 2018 showed that ~71% of the deaths globally (~41 Million people/year) are due to non-communicable diseases, predominantly cardiovascular diseases (17.9 M/year), followed by cancers (9.0 M/year). In the management of these diseases, diagnostic nuclear medicine provides invaluable information to the doctors for making an accurate diagnosis, planning treatment and monitoring patients for effective therapy.

Therapy in nuclear medicine is most often used for treating cancers and a few other conditions such as hyperthyroidism. Though therapy aims at delivering radiation dose to the target organ/lesions, it is important to ensure that the radiation dose is accurately delivered to the desired tissues. Hence, monitoring therapy through imaging is commonly followed.

Currently, nuclear medicine offers diagnostic procedures to image all the important organs and functioning of vital organs and therapeutic options for several disease conditions. Nuclear medicine imaging is also known as “molecular imaging” as it enables anatomical as well as functional (characterization and measurement of biological processes at molecular/cellular/whole organ level) evaluation. It has evolved as an important branch of medicine, providing unique and unequivocal support for patient management, especially for patients with cancers or heart diseases. This article focuses on the radionuclides currently used in nuclear medicine, as well as others now under development.

Radionuclides used in nuclear medicine

The radionuclide (RN) used in radiopharmaceuticals primarily depends on the use to which it is put (Mettler and Guiberteau, 2019). The mode of decay and the type, as well as energy of radiations emitted, are the important factors in guiding whether a radionuclide can be used in diagnostic or therapeutic NM. For diagnostic imaging, the radiation from the RN should provide information on its location, while for therapy the radiation should destroy the cells at its targeted location. The interaction of photons (Gamma rays or X-rays) with matter is quite different from the interaction of charged particles (beta electrons, positrons or alpha particles), primarily due to the charge and mass they carry. Photons are chargeless electromagnetic rays with negligible mass and are highly penetrating. When a radiopharmaceutical with a gamma emitting RN is localized inside the body, the emitted gamma radiation travels through the layers of body tissues and can provide information about the location of the radiopharmaceutical. Hence, radionuclides that decay with the emission of gamma rays can be effectively used in diagnostic imaging. On the other hand, radiations that have charge as well as mass are quickly stopped through interaction with

surrounding atoms, and they transfer their energy through such interactions. When a radiopharmaceutical with a RN that emits beta or alpha particles or Auger electrons is localized in a tissue, these radiations deposit their energy very close to their location, which in turn results in the damage or destruction of the nearby cells. The range of action would depend on the energy they carry (Saha, 2006; Nichols and Byrne, 2021). While the easy traceability of radiation and its quantitative measurement aid in diagnostic imaging, high energy transfer to the diseased cells to destroy them is necessary for therapeutic effect. Thus, the RNs ideal for use in diagnostic radiopharmaceuticals are completely different from those suitable for internal therapy.

Radioactive nuclides are unstable isotopes that undergo nuclear transformation (also referred to as transmutation or decay) to form a new nuclide at a lower energy level by emitting radiations. The difference in the energy levels of the two nuclides is carried by the radiations that emanate. The nature of the radiation emitted (α , β or γ or any combination of these) will depend on the nuclear state of the radionuclide. Radiations are energetic and travel with varying speeds, depending on their energy and their masses. The way they traverse in a medium and the mode of their energy loss will depend on the nature of the charge they carry, their mass and the medium in which they traverse. Being the most massive among the radiations mentioned above, the particulate α rays are generally highly energetic and lose their energy by collisions within a very short distance. Thus, their Linear Energy Transfer “LET” is very high and their range is very short (in microns). The particulate β rays (electrons or positrons) travel a little further than the α rays and have ranges of few millimeters, while the electromagnetic γ rays traveling at the speed of light have the maximum range.

The various applications of the radionuclides are due to one of the following characteristics:

1. radiations that are energetic and deposit their energy in the medium they travel;
2. radiations that are easily measurable at very low levels and, hence, can act as tracers; or
3. radiations that can alter the material in which they travel due to the energy deposition.
4. the radiation itself undergoes changes in its intensity and energy (attenuation of energy) depending upon the material in which it travels.

Apart from the mode of decay, the other physio-chemical parameters such as their half-life ($T_{1/2}$) and chemical feasibility to label different biological molecules influence the use of RNs in nuclear medicine. Further, for regular use in clinics, the RNs must be available in an economically viable manner. Hence, an amenable production route to avail required amounts of the RN in a pure form is important. In this context, key parameters include the route of production, their rate of production, the availability, the purity, and the isotopic abundance of the target nuclide. Radionuclidic impurities are of great concern due to the unnecessary radiation dose these impurities can impart to the patient. Based on the radiation doses delivered to critical organs, tolerance limits are set for RN impurities in RN preparations.

Desirable radionuclide properties for diagnostic nuclear medicine

For diagnostic nuclear medicine, RNs of high desirability include the following properties: they (1) emit photons that can be imaged with high sensitivity, (2) have a short half-life ($T_{1/2}$) (generally few hours to a few days), (3) exhibit amenable chemistry, and (4) are devoid of particulate emission. Gamma rays in the range of 100–200 keV energy are suitable for imaging using a gamma camera (which generally employs NaI(Tl) crystals for detection). Annihilation photons (511 keV) from positron emitters, when measured (using appropriate detectors) in a coincidence mode, provide images with high resolution. Hence, positron emitters are very useful in diagnostic nuclear medicine.

In the early stages of nuclear medicine, planar gamma cameras were used to obtain two-dimensional images of the distribution of the gamma ray emitting radiopharmaceutical inside the body and were useful in delineating abnormalities in organs, aiding in diagnosis. But, with the advances in detector and computation technologies, suitable techniques were quickly used in NM imaging to image the body with array of detectors and compute the readings to obtain three-dimensional imaging with high sensitivity. The two 3-D imaging techniques include

- A. Single Photon Emission Computed Tomography (SPECT)—where the RN is a gamma emitter used for imaging (Khalil et al., 2011); RNs emitting a single photon in high yield are preferred, and
- B. Positron Emission Tomography (PET)—where the RN is a positron emitter (Shukla and Kumar, 2006).

These two systems are commonly used in clinical NM imaging and, in many clinics, have replaced the planar gamma cameras.

In comparing these two approaches, PET images have better resolution (2–3 mm) than SPECT (4–5 mm), since the positrons result in a pair of diametrically opposite photons on annihilation and, hence, can be measured in a coincidence mode to reduce noise. Diagnostic imaging is very often used to investigate any malfunctioning tissues/lesions in the organ systems, and quantification of the radioactivity distribution is important for accurate diagnosis and treatment planning. In this context, spatial resolution and precise anatomic localization of the diseased tissue are very important. Hybrid imaging, wherein the NM imaging is carried out in conjunction with an anatomical imaging modality, such as Computed Tomography (CT), enables accurate location imaging. In the past two decades, hybrid imaging using SPECT-CT and PET-CT have become very popular and used in most NM centers regularly (Mariani et al., 2010; Farwell et al., 2014).

The following Table 1 lists the radionuclides commonly used and those with potential for use in diagnostic nuclear medicine.

Table 1 Radionuclides used in diagnostic nuclear medicine.

Gamma radiation emitting RNs suitable for single photon emission computed tomography (SPECT)					
Radionuclide	$T_{1/2}$	Decay mode	Major E_γ keV (%)	Common production route/s	Remarks
<i>Widely used</i> ^{99m}Tc	6 h	IT	140.5 (89)	$^{235}\text{U}(\text{n},\text{f})\ ^{99}\text{Mo}(\beta^-)^{99m}\text{Tc}$ $^{98}\text{Mo}(\text{n},\gamma)\ ^{99}\text{Mo}(\beta^-)^{99m}\text{Tc}$ $^{100}\text{Mo}(\text{p}, 2\text{n})^{99}\text{Mo}$ $^{100}\text{Mo}(\gamma, \text{n})^{99}\text{Mo}$	Generally availed through the ^{99}Mo - ^{99m}Tc RN Generator. ^{99}Mo $T_{1/2}$ 66 h. Tc-99m is the “work horse” of diagnostic NM. The (n,f) route yields very high specific activity Mo-99, which is preferred The (n, γ) route is used by a few institutes. Over the past decade non-fission routes for Tc-99m production are being pursued
^{111}In	2.8 days	EC	171 (93) 247 (94)	$^{112}\text{Cd}(\text{p},2\text{n})^{111}\text{In}$ $^{111}\text{Cd}(\text{p},\text{n})^{111}\text{In}$ $^{109}\text{Ag}(\alpha,2\text{n})$	The use of In-111 has been reduced after the availability of Ga-68 through a generator for PET use. But, the experience with In-111, a metallic radionuclide with +3 charge in ionic form, has been valuable to label bio-molecules with trivalent radiometals such as Ga-68, using chelating agents such as DTPA
^{123}I	13.3 h	EC	159 (83)	$^{124}\text{Xe}(\text{p},2\text{n})\ ^{123}\text{Cs} \rightarrow ^{123}\text{Xe} \rightarrow ^{123}\text{I}$ $^{124}\text{Xe}(\text{p},\text{pn})\ ^{123}\text{Xe} \rightarrow ^{123}\text{I}$ $^{123}\text{Te}(\text{p},\text{n})^{123}\text{I}$ $^{127}\text{I}(\text{p}, 5\text{n})^{123}\text{Xe} \rightarrow ^{123}\text{I}$	Reactions on Te-123 and I-127 generally yield I-123 contaminated with other isotopes of I
<i>Used in specific studies</i> ^{67}Ga	78 h	EC	93 (37) 185 (20)	$^{68}\text{Zn}(\text{p},2\text{n})^{67}\text{Ga}$ $^{67}\text{Zn}(\text{p},\text{n})^{67}\text{Ga}$	Was used for imaging acute inflammatory lesions and later to image cancer lesions. With availability of F-18-FDG (PET RN), which has better features for imaging cancerous lesions, use of Ga-67 has reduced
^{81m}Kr	13 s	IT	190 (100)	$^{82}\text{Kr}(\text{p},2\text{n})^{81}\text{Rb}(\text{EC}/\beta^+)^{81m}\text{Kr}$	Rb-81/Kr-81m generator; Rb-81 $T_{1/2}$ 4.58 h; 190 keV photons Internally converted. The short half-life of the generator and the product limits its use
^{131}I	8 days	β^-	364 (81); 637 (7)	$^{130}\text{Te}(\text{n},\gamma)\ ^{131}\text{Te}(\beta^-)^{131}\text{I}$; $^{235}\text{U}(\text{n},\text{f})^{131}\text{I}$	Useful in diagnosis as well as therapy owing to abundant gammas and the energetic beta particles. With availability of better diagnostic RNs (non-particulate emitting) use of I-131 is mostly in imaging prior to therapy of thyroid cancers (theragnostic)
^{133}Xe	5.3 days	β^- , γ	81	$^{235}\text{U}(\text{n},\text{f})^{133}\text{Xe}$	Used exclusively in Lung perfusion studies
^{201}Tl	73.1 h	EC	69–82 (95) Hg X-rays 135(3) & 167 (11)	$^{203}\text{Tl}(\text{p},3\text{n})^{201}\text{Pb}(\beta^-)^{201}\text{Tl}$ $^{\text{nat}}\text{Tl}(\text{p},\text{xn}) \dots ^{201}\text{Tl}$	Tl-201 has been specifically used only in Myocardial perfusion studies and is considered to be a gold standard
<i>Limited use</i>					

^{124}I	4.2 days	EC & β^+ (23%)	EC 603 (62.9) $\beta^+ + E_{\text{ave}}$ 2.14, 0.82 MeV	$^{124}\text{Te}(p,n)^{124}\text{I}$	Complex decay scheme of EC & β^+ ; low yield of 511 keV photons; and possible interference due to the 609 keV photon of EC. But could be a good theragnostic RN as it can be used for imaging as well as therapy with the copious Auger electrons
$^{113\text{m}}\text{In}$	1.7 h	IT	290 (100)	$^{112}\text{Sn}(n,\gamma)^{113}\text{Sn}(\beta^-)^{113}\text{In}$	^{113}Sn —118 days $T_{1/2}$; radionuclide generator; but production of Sn-113 has extremely low yields, making practical feasibility difficult

Positron emitting RNs suitable for positron emission tomography (PET)

Radionuclide	$T_{1/2}$	E_{β^+} MeV	511 keV rays%	Common production route/s	
<i>Widely used</i>					
^{18}F	110 months	0.635	194	$^{18}\text{O}(p,n)^{18}\text{F}$	Most widely used PET RN F-18-FDG is the most used PET radiopharmaceutical
^{68}Ga	68 months	1.899	178	$^{68}\text{Ga}(p,2n)^{68}\text{Ge}(\beta^-)^{68}\text{Ga}$ $^{68}\text{Zn}(p,n)^{68}\text{Ga}$	^{68}Ge $T_{1/2}$ 271 days; $^{68}\text{Ge}/^{68}\text{Ga}$ Radionuclide generator
<i>Limited specific use</i>					
^{11}C	20.4 months	0.96	196	$^{14}\text{N}(p,\alpha)^{11}\text{C}$	Since ^{11}C has a short half-life of 20 min, its use in regular clinics is limited. But, since carbon is a native element of all bio-molecules, C-11 labeled molecule would be identical to the unlabeled molecule and, hence, it is a valuable RN to study the biological behavior of molecules such as drugs
^{13}N	9.97 months	1.19	200	$^{13}\text{C}(p,n)^{13}\text{N}$	The short half-life of ^{13}N makes its routine clinical use challenging. But ^{13}N -ammonia has proven to be useful in cardiac studies and is being used via production in hospital cyclotrons
^{82}Rb	1.26 months	3.4	192	$^{85}\text{Rb}(p,4n)^{82}\text{Sr}(\beta^-)^{82}\text{Rb}$	^{82}Sr $T_{1/2}$ 25.5 days; $^{82}\text{Sr}/^{82}\text{Rb}$ Radionuclide generator; Used specifically in heart perfusion studies
<i>Emerging RNs</i>					
$^{44\text{g}}\text{Sc}^a$	3.97 h	0.632	188	$^{44/\text{nat}}\text{Ca}(p,n)^{44}\text{Sc}$ $^{45}\text{Sc}(p,2n)^{44}\text{Ti}$	^{44}Sc is of great interest as it can be a theragnostic pair with ^{47}Sc . ^a Availing ^{44}Sc through a generator from parent ^{44}Ti ($T_{1/2}$ —60 years) is attractive for clinics due to long generator shelf life. However, production of Ti-44 requires high energy cyclotrons
^{45}Ti	3.08 h	1.04	190	$^{45}\text{Sc}(p,n)^{45}\text{Ti}$	Produced using 11–16 MeV protons to avoid long-lived Ti-44. A promising RN due to ease of production

(Continued)

Table 1 Radionuclides used in diagnostic nuclear medicine.—cont'd

Positron emitting RNs suitable for positron emission tomography (PET)					
<i>Radionuclide</i>	<i>T_{1/2}</i>	<i>E_{β+} MeV</i>	<i>511 keV rays%</i>	<i>Common production route/s</i>	
⁶⁴ Cu	12.7 h	0.656	38.6	⁶⁴ Ni(p,n) ⁶⁴ Cu	Unique RN; decays by β ⁺ , β ⁻ as well as Electron Capture. Hence suitable for diagnostic as well as therapeutic NM. A good “Theranostic” RN
⁸⁶ Y	14.7 h	3.141	68	⁸⁶ Sr(p,n) ⁸⁶ Y	Theragnostic pair for Y-90, a pure beta emitter used in therapy
⁸⁹ Zr	3.27 days	0.9	45.6	⁸⁹ Y(p,n) ⁸⁹ Zr	Long half-life suitable for labeling antibodies that require long time for localization. Production amenable
¹²⁴ I	4.18 days	2.138	50	¹²⁴ Te(p,n) ¹²⁴ I	Complex decay scheme of EC & β ⁺ ; low yield of 511 keV photons and possible interference due to the 609 keV photon of EC
<i>RNs with potential for use</i> ¹⁵ O	2.03 months	1.72	200	¹⁵ N(p,n) ¹⁵ O	The half-life of ¹⁵ O is too short for routine clinical use. Yet, ¹⁵ O labeled water is deemed an ideal tracer for myocardial perfusion studies
⁷⁵ Br	96.7 months	1.721	151	⁷⁶ Se(p,2n) ⁷⁵ Br	⁷⁵ Br was explored two decades ago as a promising PET RN. But it has not progressed as expected

^aThere are two Sc-44 RNs. The metastable Sc-44m decays to the ground state Sc-44 with a half-life of 58.6 h, while Sc-44 ground state decays via positron emission or EC, with a half-life of ~4 h. Production of Sc-44 using protons or deuterons leads predominantly to the Sc-44g state. Sc-44m is produced using high energy alpha particle reactions. Currently, Sc-44g is being explored for use in PET, while Sc-44m is in the research stage. The Ti-44/Sc-44 generator route always gives Sc-44 in the ground state. Hence, it is relevant to mention Sc-44g here.

Fig. 1 Range of particulate radiations in human tissues.

Desirable radionuclide properties for therapeutic nuclear medicine

For internal therapy, radiation with high “Linear Energy Transfer” (LET) is effective. So, RNs that emit particulate radiations such as β^- , α , or electrons, combined with a half-life of a few days and amenable chemistry, are suitable for therapeutic nuclear medicine. Many RNs that decay through an electron capture path emit several low energy electrons (Auger electrons/Coster-Kronig electrons and conversion electrons) as the electron capture from the inner orbits leads to subsequent emission of X-rays and Auger or conversion electrons. These low energy electrons are also useful for therapy if the RN is in close proximity to the lesion. For selection, the therapeutic range of the RN is of importance and a RN with therapeutic range matching with the size of the lesions to be treated is chosen.

Fig. 1, showing the range of different particles in tissues, illustrates the importance of choosing the appropriate radionuclide based on the target tissue size.

A wide range of RNs are suitable for NM therapy applications (Goldsmith, 2019). But the factors mentioned earlier, such as half-life, feasibility of production, availability in reasonably pure form without other RN impurities, and amenability to tag to suitable bio-molecules, dictate the actual use in clinical practice. Most of the current approved therapeutic radiopharmaceuticals are tagged with beta emitting RNs, with a preference to those that also emit an imageable photon—since this allows monitoring of the localization of the radiopharmaceutical as well as the ability to calculate the dose delivered to the target and different vital non-target organs.

In recent times, there has been a lot of attention on targeted alpha therapy, as alpha particles have high LET. One alpha emitting radiopharmaceutical ($^{223}\text{Radium chloride}$ for bone pain palliation) is approved (Deshayes et al., 2017), while several are under clinical trials.

The commonly used and significantly explored radionuclides in therapeutic nuclear medicine are listed below in **Table 2**.

In the case of therapy, the type and energy of radiation influence the range of therapeutic action. **Table 3** provides a brief perspective of therapeutic RNs based on the range of action.

Thera(g)nostics

The practice of therapeutic NM is moving towards personalized therapy. The key for effective therapy includes (1) ensuring that the therapeutic radiopharmaceutical will localize in the target tissue, and (2) the ability to calculate accurate delivery of the radiation dose. This is achieved by an appropriate diagnostic evaluation, followed by the administration of a suitable therapeutic radiopharmaceutical in an amount calculated based on the diagnostic evaluation. For the best outcome, the same biomolecule is used for imaging as well as therapy, but labeled with suitable radionuclides of the same element or surrogate nuclides. This combination of diagnostic and therapeutic procedures for planning personalized treatment is known as “Thera(g)nostics.” Here a matched pair of nuclides (which could either be of the same element or a surrogate element) are used (Yordanova et al., 2017; Ballinger, 2018). See more on Thera(g)nostics in (Kang and Venkatesh, 2021). **Table 4** lists the RNs for use as “thera(g)nostic” pairs.

Production of radionuclides

Naturally occurring RNs are seldom useful in healthcare applications. The RNs used in medicine are artificially produced either in research reactors (Barradas, 2021) or charged particle accelerators (Garcia, 2021) or availed from a radionuclide generator (the parent nuclide in the radionuclide generator is produced either in a reactor or an accelerator and the daughter nuclide is the RN used in NM).

Table 2 Radionuclides used in therapeutic nuclear medicine.

Radionuclide	$T_{1/2}$	Decay mode	$E_{\beta\max}$ (MeV)	Common production route/s	Remarks
<i>Widely used</i> ^{131}I	8.03 days	β^- , γ	0.606 (major beta)	$^{130}\text{Te}(n,\gamma) \rightarrow ^{131}\text{Te} (\beta^-) ^{131}\text{I}$; $^{235}\text{U}(n,f) ^{131}\text{I}$ $^{176}\text{Lu}(n,\gamma) ^{177}\text{Lu}$; $^{176}\text{Yb}(n,\gamma) ^{177}\text{Yb} \rightarrow \beta^- ^{177}\text{Lu}$	Well established for treatment of thyroid cancers. I-131 labeled molecules used in certain specific cancers
^{177}Lu	6.64 days	β^- , γ	0.497		Growing use in therapy of different cancers
<i>Established, limited specific use</i> ^{32}P	14.3 days	β^-	1.71	$^{32}\text{S} (n,p) ^{32}\text{P}$	High energy neutrons needed Primarily used in the past for treating polycythemia vera. In some countries currently used for palliative treatment of skeletal metastases
^{89}Sr	50.5 days	β^-	1.46	$^{89}\text{Y}(n,p) ^{89}\text{Sr}$ $^{88}\text{Sr}(n,\gamma) ^{89}\text{Sr}$	High energy neutrons needed for (n,p) reaction; well established for palliative treatment of skeletal metastases
^{90}Y	2.67 days	β^-	2.27	$^{235}\text{U}(n,f) \rightarrow ^{90}\text{Sr} (\beta^-) ^{90}\text{Y}$ $^{89}\text{Y}(n,\gamma) ^{90}\text{Y}$	^{90}Sr $T_{1/2}$ 29.9 years; $^{90}\text{Sr}/^{90}\text{Y}$ Radionuclide Generator; Used for treatment of large size lesions, especially for liver cancers
^{153}Sm	1.9 days	β^- , γ	0.81	$^{152}\text{Sm}(n,\gamma) ^{153}\text{Sm}$	Primarily used as phosphonate for palliative treatment of skeletal metastases
^{169}Er	9.3 days	β^-	0.34	$^{168}\text{Er}(n,\gamma) ^{169}\text{Er}$	Extremely specific use in radiation synoviorthesis to treat small phalangeal joints
^{188}Re	17.0 h	β^- , γ	2.12	$^{186}\text{W}(n,\gamma) ^{187}\text{W}(n,\gamma) ^{188}\text{W} (\beta^-) ^{188}\text{Re}$ $^{187}\text{Re}(n,\gamma) ^{188}\text{Re}$	^{188}W $T_{1/2}$ 69 days; $^{188}\text{W}/^{188}\text{Re}$ Radionuclide Generator; ^{188}W production involves successive neutron capture and, hence, feasible in high flux reactors
$^{225}\text{Ac} \downarrow$	9.92 days	α	5.83	Radiochemical extraction of ^{225}Ac from ^{229}Th ($T_{1/2} = 7917$ years) from spent fuel/stock of nuclear materials	RN of great interest in recent times; excellent results in treatment of prostate cancers when labeled with PSMA, a peptide specific to prostate cancer; availability in huge amounts remains a challenge
^{213}Bi (see Fig. 2 below)	45.6m	β^- (97.8%) α (2.2%)	1.42(β^-) 5.875(α)	$^{226}\text{Ra}(p,2n) ^{225}\text{Ac}$ $^{227}\text{Ac} (\beta^-) ^{227}\text{Th}(\alpha) ^{223}\text{Ra}$ $^{226}\text{Ra}(n,\gamma) ^{227}\text{Ra}(\alpha) ^{223}\text{Ac} \downarrow (\beta^-)$ $^{223}\text{Th}(\beta^-) ^{223}\text{Ra}$	^{213}Bi is a daughter product in the decay series and, hence, an Ac-225 tagged radiopharmaceutical would have the therapeutic effect of Bi-213 Bi-213 as a therapeutic RN is also being pursued strongly
^{223}Ra	11.43 days	α	5.72		$^{227}\text{Ac}-^{227}\text{Th}-^{223}\text{Ra}$ generator system is used; but ^{223}Ra is expensive, as ^{227}Ac is difficult to obtain. The $T_{1/2}$ of ^{227}Ac is 22 y and of ^{227}Th is 19 days, which is also a potential therapy RN Specifically used in palliative treatment of skeletal metastases in the form of Radium chloride. ^{223}Ra decays in a chain through emission of 4 α and 2 β -particles to stable ^{207}Pb . The total energy emitted in the sequence is 28.2 MeV (see Fig. 3 below)

<i>Emerging RNs</i> ^{47}Sc	3.35 days	β^- , γ	0.6	$^{46}\text{Ca}(n,\gamma)^{47}\text{Ca} \rightarrow ^{47}\text{Sc}$ $^{47}\text{Ti}(n,p)^{47}\text{Sc}$	Thera(g)nostic pair of Sc-4
^{67}Cu	2.58 days	β^- , γ	0.57	$^{67}\text{Zn}(n,p)^{67}\text{Cu}$ $^{68}\text{Zn}(p,2p)^{67}\text{Cu}$	Thera(g)nostic pair of Cu-64; growing interest
<i>RNs with therapeutic potential-explored/limited use/identified</i>					
^{105}Rh	1.47 days	β^- , γ	0.57	$^{104}\text{Ru}(n,\gamma)^{105}\text{Ru} (\beta^-)^{105}\text{Rh}$	The beta particles from ^{105}Rh are attractive for therapy; however, radiolabeling bio-molecule with the soft metal Rh(I) is not very amenable
$^{117\text{m}}\text{Sn}$	13.6 days	IT and IC	IC e^- 130, 160, E_γ 159 keV	$^{117}\text{Sn}(n,n\gamma)^{117\text{m}}\text{Sn}$	Very low reaction cross section and yields. Primarily used for palliative treatment of skeletal metastases
^{143}Pr	13.6 days	β^-	1	$^{142}\text{Ce}(n,\gamma)^{143}\text{Ce} (\beta^-)^{143}\text{Pr}$	One of the radiolanthanides with therapeutic potential; but not explored much
^{165}Dy	2.33 h	β^- , γ	1.285	$^{164}\text{Dy}(n,\gamma)^{165}\text{Dy}$	The photon emission is very low and of low energy
^{166}Ho	26.9 h	β^- , γ	1.85	$^{165}\text{Ho}(n,\gamma)^{166}\text{Ho}$	γ rays of 81 keV (6.4%) helps in imaging and dosimetry
^{170}Tm	128.6 days	β^- , γ	0.968 (82%), 0.883 (18%)	$^{169}\text{Tm} (n,\gamma)^{170}\text{Tm}$	Although the half-life of 129 days is generally not preferred, it is useful in pain palliation
^{175}Yb	4.18 days	β^- , γ	0.47	$^{174}\text{Yb}(n,\gamma)^{175}\text{Yb}$	The $T_{1/2}$ and 390 keV γ emission in low fraction are advantageous for therapy
^{186}Re	3.72 days	β^- , γ	1.07	$^{185}\text{Re}(n,\gamma)^{186}\text{Re}$	Small percentage (9.5%) γ with energy 137 keV is very useful. But, production logistics not amenable
^{198}Au	2.69 days	β^- , γ	0.96	$^{197}\text{Au} (n,\gamma)^{198}\text{Au};$	Useful for therapy; but E_γ 412 keV is high
^{211}At	7.21 h	EC(58.2%) α (41.8%)	0.687 (EC- γ) 5.87 (α)	$^{209}\text{Bi}(\alpha,2n)^{211}\text{At}$	At-211, a radiohalogen, has been explored for labeling in a similar way as I-131
^{213}Bi	45.6 months	β^- (97.8%) α (2.2%)	1.42(β^-) 5.875(α)	$^{225}\text{Ac}(3\alpha)^{213}\text{Bi}$ (see Fig. 2)	^{213}Bi is short lived α emitter availed from Ac-225. Therapy using both the RNs is an approach followed
^{227}Th	18.7 days	α	6.038	$^{227}\text{Ac} (\beta^-)^{227}\text{Th}(\alpha)^{223}\text{Ra}$ (see Fig. 3)	^{227}Th is an intermediate product in the decay chain of Ac-227 and has the potential to be used for therapy

Fig. 4 U-235 Fission Yield Curve.

Fig. 2 Decay scheme of Ac-225.

Radionuclide production in nuclear reactors

As mentioned earlier, the use of radionuclides in medicine has a long history. With the establishment of research reactors, several radioisotopes were produced and supplied to the hospitals. The most used were Phosphorus-32, Iodine-131, Gold-198, Chromium-51, Sodium-24 and Mercury-198; and among these, I-131 continues to be an important therapeutic radioisotope, and Phosphorus-32 is still used in a few countries for therapy. The rest are currently seldom used in radiopharmaceuticals, although in recent years there has been a revival of interest in the use of the emitting **what?** for in vivo therapy.

In nuclear reactors, reactions induced by neutrons (such as radiative neutron capture (n, γ); neutron capture followed by beta decay ($n, \gamma \rightarrow \beta^-$); neutron capture followed by a proton emission (n, p); neutron capture followed by an alpha particle

Table 3 Important therapeutic radionuclides in terms of nature of emission and tissue range.

	Radionuclides
ALPHA EMITTERS ($E_\alpha = 5\text{--}8$ MeV; 40–80 μm range)	^{211}At , ^{212}Bi , ^{213}Bi , ^{256}fm , ^{225}Ac , ^{223}Ra
BETA EMITTERS (range: 1–12 mm)	
Hard betas (E_β max over 1.5 MeV)	^{32}P , ^{90}Y , ^{188}Re , ^{166}Ho , ^{89}Sr , ^{142}Pr
Medium betas (E_β max 0.5–1.5 MeV)	^{131}I , ^{153}Sm , ^{186}Re , ^{89}Sr , ^{170}Tm , ^{67}Cu , ^{143}Pr
Soft betas (E_β max less than 0.5 MeV)	^{33}P , ^{169}Er
Auger Electrons/Conversion Electrons Emitters (range: nm to μm)	^{124}I , ^{125}I , $^{117\text{m}}\text{Sn}$

Table 4 Thera(g)nostic pairs: therapeutic radionuclides and surrogate radionuclides for diagnostic imaging for internal dosimetry.

Therapeutic RN	$T_{1/2}$	Decay mode	E_γ/keV (%) for imaging	Diagnostic pair	$T_{1/2}$	Decay mode	Surrogate RN E_γ/keV (%)
<i>Therapeutic radionuclides with gamma emission which can be imaged</i>							
^{131}I	8 days	β^-	365 (82)	^{123}I	13.3 h	EC	159 (83)
				^{124}I	4.15d	EC and β^+	603 (62.9)
							511 (23)
^{47}Sc	3.35 days	β^-	159 (68)	^{44}Sc	3.97 h	β^+	511 (188)

							511 (23)
^{89}Sr	50.5 days	β^-		^{85}Sr	64.9d	EC	514 (96)
				$^{87\text{m}}\text{Sr}$	2.8 h	IT	388 (82)

^a ^{64}Cu decays by three different modes, namely β^- , β^+ , as well as Electron Capture and emits beta rays, positrons as well as gamma rays, which can be used for both diagnostic and therapeutic purpose.

emission (n, α); and nuclear fission (n, f)) are used for the production of RNs. Often, the products are neutron rich isotopes, which would transmute through beta decay. In nuclear reactors, the most commonly used routes for production of RNs are (n, γ) or (n, γ) $\rightarrow \beta \rightarrow$ reactions.

But, the fission of U-235, which results in a wide range of radioisotopes with varied yields, peaking around mass numbers 100 and 130, as shown in the adjoining Fig. 4, is an attractive route for producing RNs in the peak regions as the yields are excellent. Fission has been the principal route for production of Mo-99 (parent of Tc-99m) and a few other radioisotopes such as I-131, Xe-133.

Radionuclide production in accelerators

Protons and deuterons of energies between 10–30 MeV are the most employed charged particles for the production of clinically used RNs in dedicated medical cyclotrons. Often, small cyclotrons, also known as baby cyclotrons, are installed in hospital set-up to avail a smooth supply of such RNs. (The IAEA Medical cyclotrons directory gives the list of cyclotron facilities in the world). The proton/deuteron induced reactions with emission of neutrons ((p, n), (d, n), (p, xn) etc.) are the most common routes used, leading to neutron deficient RNs, which predominantly decay through positron emission or electron capture routes.

Fig. 3 Decay scheme of Ac-227.

Table 1 lists several examples of such reactions. Alpha particles have also been used for the production of a few RNs. For example, production of Ga-68 and Sm-153 have been reported through (α, n) reaction ($^{65}\text{Cu}(\alpha, n)^{68}\text{Ga}$; $^{150}\text{Nd}(\alpha, n)^{153}\text{Sm}$) (Qaim, 2017). However, heavy ion induced reactions often require higher energy cyclotrons and may not be economically attractive for regular production, especially if there is an alternate method. With the quest for additional suitable RNs for use in NM, higher energy particle reactions in larger cyclotrons (including spallation reactions), linear accelerators, and electron accelerators are being increasingly explored and employed for their production.

Although several RNs could be used in NM, as seen from the tables above, not all of them are used in clinical settings on regular basis, despite good features. Several factors that influence the feasibility of production of a RN in NM in clinical practice were mentioned earlier, underlining the need for producing the RN in high purity. In this context, the use of enriched targets often helps to avoid unwanted radionuclide impurities. But, enriched targets are generally expensive and, in some cases, where the natural abundance is low, enriched targets can be extremely expensive—making the cost of the procedure very high and, hence, unfavorable for routine clinical use. In the case of therapy using RNs, the therapeutic range depends on the type of radiation and its energy, and often the RN is chosen depending on the desired volume to be irradiated.

Radionuclide generators in nuclear medicine

“Radionuclide generators” are very convenient devices to produce a RN at the user end (hospital or a radiopharmacy). Such RN generators are possible when a parent RN with a longer half-life decays to the daughter RN with shorter half-life. The daughter nuclide grows and reaches a maximum—beyond which its growth and decay match and nullify each other and, hence, reaches an equilibrium state after a time that is dictated by the half-lives of the pair. The daughter nuclide can be repeatedly harvested after suitable time gaps and used for preparation of the radiopharmaceuticals, which makes the RN generators an attractive option to produce the RN at will. Availability as a generator has been one of the important factors that steered the growth of the generator availed RNs in NM. The $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator is an excellent example.

Radionuclide generators are very convenient to avail short lived medical radionuclides at will. Hence, they provide an attractive option for the hospitals/radiopharmacies since it is not dependent on transport from a reactor or cyclotron—even though the parent radionuclides have to be produced in reactors or cyclotrons (Lambrecht, 1983; Rösch and Knapp, 2011). As mentioned earlier, for a useful generator, the parent nuclide has to be longer-lived than the shorter-lived daughter nuclide, such that the daughter nuclide can be periodically separated and used in preparation of radiopharmaceuticals. The daughter nuclide, which is of interest, is produced due to the decay of the parent nuclide. Its potency is then depleted due to its own decay.

Consider the decay constant of the parent nuclide to be λ_1 and that of the daughter to be λ_2 . If there are N_1 atoms of the parent nuclide, the rate at which it decays to the daughter nuclide can be expressed as $N_1\lambda_1$ (and this is the same as the rate of production of the daughter nuclide). The rate at which the daughter nuclide decays is $N_2\lambda_2$. The overall growth rate of the daughter nuclide can be expressed as

$$\frac{dN_2}{dt} = N_1\lambda_1 - N_2\lambda_2$$

If the half-life of the daughter nuclide is shorter than the parent nuclide, the daughter nuclide grows initially from the point when there is just the parent nuclide ($N_1 = N_1^0$ and $N_2 = N_2^0 = 0$) and with time the amount of N_2 increases, until the rate of growth and depletion of the daughter nuclide are nearly equal. This state is known as "equilibrium." The time taken to reach this equilibrium would be a function of the decay constants of the parent-daughter pair.

We can write mathematical equations to represent the amounts of the parent and daughter at any point of time "t," wherein at time $t = 0$, the beginning, $N_1 = N_1^0$ and $N_2 = N_2^0$ (which is equal to 0 when one starts with pure parent nuclide. However, this equation is valid only when N_2^0 amount of daughter nuclide is present in the system at time $t = 0$).

$$\frac{dN_1}{dt} = -N_1\lambda_1 \text{ and } \frac{dN_2}{dt} = N_1\lambda_1 - N_2\lambda_2$$

On integration of these equations, one gets $N_1 = N_1^0 e^{-\lambda_1 t}$ and

$$N_2 = \lambda_1 / (\lambda_2 - \lambda_1) N_1^0 (e^{-\lambda_1 t} - e^{-\lambda_2 t}) + N_2^0 e^{-\lambda_2 t}$$

When $N_2^0 = 0$, $N_2 = \lambda_1 / (\lambda_2 - \lambda_1) N_1^0 (e^{-\lambda_1 t} - e^{-\lambda_2 t})$

If λ_2 is considerably greater than λ_1 , and when the time elapsed is long (several folds longer than the half-life of the daughter nuclide), then the term $e^{-\lambda_2 t}$ is negligible in comparison to $e^{-\lambda_1 t}$, and the equation can be approximated to

$$N_2 = \frac{\lambda_1}{\lambda_2 - \lambda_1} N_1^0 e^{-\lambda_1 t}$$

Since $N_1^0 e^{-\lambda_1 t} = N_1$, the equation can be written as

$$N_2 = \frac{N_1\lambda_1}{(\lambda_2 - \lambda_1)}; \quad \text{which is} \quad \frac{N_1}{N_2} = \frac{\lambda_2 - \lambda_1}{\lambda_1}$$

Thus, it can be seen that when a considerable amount of time elapses, the ratio of parent and daughter nuclides reaches a constant value (equilibrium). When the half-life of parent is far greater (there is no specific number, but can be considered to be orders of magnitudes greater) than that of daughter, the equilibrium is known as "Secular" equilibrium. When it is moderately greater, the equilibrium is known as "Transient."

If the above equation is expressed in terms of "activity" (disintegrations per second or Bq), it will be $\frac{N_2\lambda_2}{\lambda_2} = \frac{N_1\lambda_1}{(\lambda_2 - \lambda_1)}$; or $\frac{A_2}{\lambda_2} = \frac{A_1}{(\lambda_2 - \lambda_1)}$; $A_2 = \frac{A_1\lambda_2}{(\lambda_2 - \lambda_1)}$

This indicates that when sufficient time has elapsed and equilibrium is established, the parent and daughter activities are in a constant ratio. If λ_2 is considerably greater than λ_1 , the above equation can be further approximated to $A_2 = A_1$. The time required to attain equilibrium and reach this maximum level, also known as $t_{\max}$ is given by the equation

$$t_{\max} = \frac{1}{\lambda_2 - \lambda_1} \ln \frac{\lambda_2}{\lambda_1}$$

As a general approximation, it is considered that the time to reach equilibrium is about four times the $T_{1/2}$ of the daughter RN in the case of transient equilibrium, and about seven times the $T_{1/2}$ of the daughter RN in the case of secular equilibrium.

The graph of N_1 and N_2 with time would look like the following Figs. 5 and 6 for both cases.

Fig. 5 Transient equilibrium.

Fig. 6 Secular equilibrium.

Fig. 7 Growth of daughter RN with time on repeated elution.

Once the daughter nuclide grows to the maximum (no effective growth when rate of growth and decay are equal), it is “harvested” by separating it from the parent, setting the time back to “zero” ($N_2 = 0$) and it starts growing again. A graph of the activity growth is represented below in **Fig. 7**.

The daughter nuclide is thus availed repeatedly, and this phenomenon has been compared with daily milking of cows. Separation of the daughter nuclide is at times referred to as “milking” and the generator as “cow.” In the case of Tc-99m, with a half-life of ~ 6 h, the t_{max} is ~ 23 h and the Mo-99/Tc-99m generator can be indeed “milked” every morning at the radiopharmacy. The useful shelf life of the generator will depend on the half-life of the parent; and the time required for the daughter RN to grow to the equilibrium state depends on the half-life of the daughter, which guides the frequency at which it can be separated and used. Isolation of the daughter nuclide from the parent is most often achieved through chromatographic elution from a column using suitable eluants, although a few other separation mechanisms such as solvent extraction, electrochemical separation, sublimation, conversion of the parent RN into a solid matrix are amenable for use as the column matrix or membrane separation have been used and explored ([Dash and Chakravarty, 2014](#)).

While several separation techniques may be used to efficiently separate the daughter nuclide from the parent, the practical usage will depend upon the ease of production as well as the ease of operation, with minimal radiation exposure to the personnel. Hence, generators that can be manufactured in large numbers, are portable, safe, cost effective, and which can be handled with ease by the users are the ones used widely. Column chromatography-based generators, where the daughter RN can be eluted by connecting an evacuated vial at the end of the column, are the most used.

It is important to separate the daughter nuclide of interest from the parent nuclide with high purity, both chemically as well as radio nuclidic purity. It is possible to avoid radionuclide impurities when the parent and the daughter nuclides are of different elements, which is the case in all the generators used in nuclear medicine. The permissible limit for the parent RN in the daughter RN (often referred to as parent RN breakthrough in the daughter eluate) depends on the undesired effects of the parent RN. The unwanted radiation dose from the parent RN, which in turn would be dependent on the target organs

where it would accumulate and its half-life, are the prime factors that govern the tolerance limits set for parent RN in the daughter RN product. For example, the limit for ^{99}Mo in $^{99\text{m}}\text{Tc}$ eluate is 0.15%, whereas the limit for ^{90}Sr in ^{90}Y is extremely low, less than $10^{-4}\%$, since ^{90}Sr has a half-life of 28.5 years and Sr^{+2} accumulates in bone and stays there for decades, giving a potentially serious radiation dose to bone marrows. The limits for ^{90}Sr in ^{90}Y are set based on the bone marrow radiation dose from ^{90}Sr (Pandey et al., 2008).

The quality control tests used are designed to measure such extremely low levels of the undesired RNs. Further, quality control tests are also performed to ensure that the levels of the possible chemical impurities are lower than the permissible levels. For example, if a column chromatography generator is used, the amount of adsorbent that gets eluted into the daughter product is limited; and if a solvent extraction separation is used, the amount of the solvent used for extraction is limited—the limits being set up based on the permissible levels of these chemicals in an injectable.

A list of RN generators used/potential for use in nuclear medicine is provided in Table 5 (not an exhaustive list):

Some of these generators are in regular use and commercially supplied, while several others have been and are being explored for use in NM, but are yet to be used in a sustainable manner in NM. Although the daughter RN may have the potential for use, the practical aspect, such as the feasibility of producing the parent RN in high purity and in adequate quantities, is an important factor for sustainable production and use of RN generators. Further, RNs with very short half-life pose a great challenge in their use. The concept of “in vivo” generator, wherein the parent RN is used for preparation of the radiopharmaceutical and administered in the patient, has been explored in a few cases where the daughter RN has a very short half-life (and, hence, would decay before the molecule reaches the target) (Mausner et al., 1989; Edem et al., 2016). However, this approach requires the molecules labeled with parent and daughter nuclides to have similar in vivo behavior, which is often not the case due to different chemical features of the parent and daughter RNs.

The commonly used generators are briefly described below.

Table 5 Radionuclide generators relevant to nuclear medicine.

Generator	Parent $T_{1/2}$	Decay mode	Daughter $T_{1/2}$	Decay mode	E_{γ} (keV)
<i>Generators for gamma emitting RNs for SPECT/gamma imaging</i>					
$^{99}\text{Mo}/^{99\text{m}}\text{Tc}$	65.9 h	β^{-}	6.01 h	IT	140.5
$^{81}\text{Rb}/^{81\text{m}}\text{Kr}$	4.57 h	EC	13.1 s	IT	190.6
$^{77}\text{Br}/^{77\text{m}}\text{Se}$	57 h	EC	17.4 s	IT	161.9
$^{109}\text{Cd}/^{109\text{m}}\text{Ag}$	1.265 years	EC	39.8 s	IT	88
$^{113}\text{Sn}/^{113\text{m}}\text{In}$	115.1 days	EC	1.66 h	IT	391.7
$^{178}\text{W}/^{178\text{m}}\text{Ta}$	21.6 days	EC	2.36 h	EC(99%), β^{+}	97.3
$^{191}\text{Os}/^{191\text{m}}\text{Ir}$	15.4 days	β^{-}	4.9 s	IT	171.3
<i>Generators for positron emitting RNs for PET imaging</i>					
$^{68}\text{Ge}/^{68}\text{Ga}$	270.9 days	EC	67.7 min	β^{+} (89%), EC	511
$^{82}\text{Sr}/^{82}\text{Rb}$	25 days	EC	1.25 min	β^{+} (96%), EC	511, 776
$^{44}\text{Ti}/^{44}\text{Sc}$	47/60.0 years	EC	3.93 h	β^{+} (95%), EC	511, 1157
$^{52}\text{Fe}/^{52\text{m}}\text{Mn}$	8.3 h	β^{+} (56.5%), EC(43.5%)	21 min	β^{+}	511, 1434
$^{162}\text{Zn}/^{62}\text{Cu}$	9.2 h	β^{+} (6.9%), EC(93%)	9.73 min	β^{+} (97.8%), EC	511
$^{72}\text{Se}/^{72}\text{As}$	8.4 days	EC	26 h	β^{+} (77%), EC	511, 834
$^{110}\text{Sn}/^{110\text{m}}\text{In}$	4.11 h	EC	69 min	β^{+} (62%), EC	511, 658
$^{118}\text{Te}/^{118}\text{Sb}$	25 days	EC	3.5 min	β^{+} (76%), EC	511
$^{122}\text{Xe}/^{122}\text{I}$	20.1 h	EC	3.6 min	β^{+} (77%), EC	511
$^{128}\text{Ba}/^{128}\text{Cs}$	2.43 days	EC	3.64 min	β^{+} (53%), EC	511
$^{134}\text{Ce}/^{134}\text{La}$	3.16 days	EC	6.45 min	β^{+} (62%), EC	511
$^{140}\text{Nd}/^{140}\text{Pr}$	3.37 days	EC	3.39 min	β^{+} (51%), EC	511
<i>Generators for therapeutic RNs</i>					
$^{90}\text{Sr}/^{90}\text{Y}$	28.5 years	β^{-}	2.67 days	β^{-}	E_{max} (MeV) 2.218
$^{188}\text{W}/^{188}\text{Re}$	69.4 days	β^{-}	16.9 h	β^{-}	2.118
$^{66}\text{Ni}/^{66}\text{Cu}$	54.6 h	β^{-}	5.1 month	β^{-}	2.6
$^{112}\text{Pd}/^{112}\text{Ag}$	21.0 h	β^{-}	3.1 h	β^{-}	3.94
$^{115}\text{Cd}/^{115\text{m}}\text{In}$	2.23 days	β^{-}	4.49 h	β^{-}	0.83
$^{140}\text{Ba}/^{140}\text{La}$	12.75 days	β^{-}	1.68 days	β^{-}	1.35
$^{194}\text{Os}/^{194}\text{Ir}$	6.0 years	β^{-}	19.28 h	β^{-}	2.23
$^{224}\text{Ra}/^{212}\text{Bi}^{\text{a}}$	3.63 days	α	60.55 min	α , β^{-}	α (6.0); β^{-} (2.25)
$^{225}\text{Ac}/^{214}\text{Bi}^{\text{a}}$	9.92 days	α	19.9 min	α , β^{-}	α (5.83); β^{-} (3.27)
$^{227}\text{Ac}/^{223}\text{Rn}^{\text{a}}$	21.77 years	α	11.43 d	α	5.72

^aIn these generators, the first parent indicated here undergoes a series of alpha decays to yield the daughter RN of interest, indicated here. This can be seen from the decay schemes of Ac-225 and Ac-227 given earlier.

$^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ Generator

$^{99\text{m}}\text{Tc}$ is an ideal radionuclide, used in a wide variety of radiopharmaceuticals (details given under Tc-99m later in this article) and the $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator is the most used generator in nuclear medicine. The ^{99}Mo (half-life 66 h/2.75 days)— $^{99\text{m}}\text{Tc}$ (half-life 6 h) pair attains transient equilibrium and the amount of daughter $^{99\text{m}}\text{Tc}$ reaches a maximum at nearly 23.5 h, which is practically very convenient. The terms “cow” to indicate the generator and “milking” to refer to the separation of the daughter nuclide, fit well in this case, as generally $^{99\text{m}}\text{Tc}$ is separated daily for preparation of radiopharmaceuticals. Different techniques, such as column chromatography, solvent extraction, sublimation and electrochemical separation have been used to separate $^{99\text{m}}\text{Tc}$ from ^{99}Mo (Boyd, 1982; Le, 2014; IAEA TECDOC-852, 1995). Among these, column chromatography generators with alumina as the sorbent and saline as the eluant are the most widely used. The specific activity of the Mo-99 is a key factor that has an impact on the separation efficiency.

In brief, the adsorbent used in the column binds to Mo-99 strongly while the daughter Tc-99m is not bound, which makes it possible to elute the daughter from the column using a suitable solvent, such as saline. As the capacity to bind to the parent Mo-99 is limited, an adequate amount of the sorbent needs to be used in the column to hold the amount of molybdenum. Mo-99 obtained from fission of uranium is of high specific activity and has extremely low amounts of molybdenum, enabling use of a small amount of sorbent (few grams of alumina) per generator. Low specific activity Mo-99 from the neutron activation route would have far higher amounts of molybdenum and would need much larger amounts of adsorbent making the column long and the eluted Tc-99m dilute (low specific volume). For radiolabeling molecules, Tc-99m must be adequately concentrated. Hence, column chromatography generators with alumina as the adsorbent are not suited to avail Tc-99m from low specific activity Mo-99 without post elution concentration of the eluted Tc-99m. Other adsorbents based on metallic oxides and nanocrystalline materials have been explored with limited success; but none have been adopted to commercial production and supply. Several other separation technology options have also been explored in this context.

In the other technologies, such as sublimation, solvent extraction, and electrochemical separation, Tc-99m is obtained in a concentrated form. Converting the low specific activity Mo-99 into a chemical form that is amenable to be used as the column matrix has been explored, and zirconium molybdate has been successfully used to prepare column generators, also termed as “gel generators,” but deployed in a few limited institutes (Evans et al., 1987; Saraswathy et al., 1998). Mo-99-Tc-99m generators continue to be of interest to researchers, especially as production of Mo-99 through non-fission is being explored.

 $^{81}\text{Rb}/^{81\text{m}}\text{Kr}$ Generator

Kr-81m, a noble gas with a half-life of just 13 s, is used predominantly in lung imaging (Koyama et al., 1980). As the half-life of the parent Rb-81 is also short, 4.7 h, the useful life of the generator is just about a day (Ruth et al., 1980), making it a challenge to produce and transport the generator to hospitals. Hence, the manufacture and the use of this generator is limited. The permissible level of Rb-81 in the Kr-81m product is less than 0.1%.

 $^{68}\text{Ge}/^{68}\text{Ga}$ Generator

Ga-68 has gained a lot of attention in the past decade (more on Ga-68 under radionuclides below) (Rösch, 2013). A key factor for its increased use is the availability through the generator, especially because the long half-life of 271 days of the parent Ge-68 translates to long useful shelf-life of the generator and assured supply of the short lived (67.7 min half-life) Ga-68 over several months. The currently available Ge-68/Ga-68 generators are of the column chromatography type and different adsorbent matrices such as titanium dioxide or tin dioxide, as the adsorbent matrix, and hydrochloric acid as the eluant (Romero et al., 2020). The daughter Ga-68 growth reaches the maximum level in 7 h and, hence, can be eluted a few times every day. The gallium, eluted as Ga(III) chloride. The permissible amount of Ge-68 in the Ga-68 product is not strictly specified, but a value of less than 0.01% breakthrough of Ge-68 is considered acceptable. Most commercial generators report far lesser breakthrough values.

 $^{82}\text{Sr}/^{82}\text{Rb}$ Generator

Rb-82, a positron emitter, is used in myocardial perfusion imaging studies (Alvarez-Diez et al., 1999; Yoshinaga et al., 2010). Rb-82 has a half-life of just 1.25 min., making its administration into the patient a challenge. But, as the parent RN Sr-82 has a half-life of 25 days, the generator has a reasonably long useful life of about 6–8 weeks. The current Sr-82/Rb-82 generators are chromatographic generators with titanium oxide as the column material and eluted with normal saline. The permissible limits for the strontium radionuclides Sr-82 and Sr-85 in the Rb-82 eluate are $2 \times 10^{-4}\%$ and $2 \times 10^{-3}\%$ respectively. The use of Sr-82/Rb-82 generator, which was limited owing to the short half-life of Rb-82, witnessed a renewed interest in catering to the myocardial imaging that faced challenges due to the shortages of supply of Mo-99/Tc-99m generators, during 2007–08 period. Although the supply of Mo-99/Tc-99m generators has resumed to cater to demands, several users continue to use the Sr-82/Rb-82 generators.

 $^{90}\text{Sr}/^{90}\text{Y}$ Generator

Y-90, with a half-life of 64 h, emits high energy beta particles and is ideal for RN therapy of large lesions. The parent Sr-90 has a long half-life of 28.5 years, and, hence, the Sr-90/Y-90 generators would theoretically have an exceptionally long shelf life. However, in

practice, the usability of a generator will depend on the type of generator and the storage of the parent RN. If the generator is of column chromatography type, in which the parent RN is adsorbed in a solid matrix, the integrity and performance of the matrix could be affected by radiation and, hence, this aspect will have to be considered in the use of the generator. Nevertheless, the long half-life of Sr-90 makes it a possible to separate the daughter Y-90 repeatedly for several decades, longer than the half-life of Sr-90. Different types of generators have been reported (IAEA TECDOC TRS 470, 2009), based on separation systems such as ion-exchange column chromatography (Chinol et al., 1997), electrochemical separation (Chakravarty et al., 2008), and membrane-based separation (Dhami et al., 2007). Currently, the Sr-90/Y-90 generators are prepared and operated at the nuclear institutes or radiopharmaceutical manufacturing centers and not commercially available, although Y-90 is commercially available for radiolabeling at the user end. As Sr-90 is also a beta emitter and an analog of calcium, it would accumulate in the bone and stay there for long if administered along with Y-90. Hence, based on the maximum permissible body burden of 74 kBq (2 μ Ci) for Sr-90, the permissible limit for Sr-90 in Y-90 is extremely low (less than $10^{-4}\%$), as the total amount of Y-90 administered is generally large over several cycles of treatment.

¹⁸⁸W/¹⁸⁸Re Generator

Re-188 emits high energy beta particles and is well suited for therapy of large lesions. The 16.9 h half-life of Re-188 and the 69 days half-life of parent W-188, makes this generator system a very convenient one with a long shelf life, with the possibility of availing Re-188 frequently. The major challenge is the production of W-188 by double neutron capture on W-186, which yields a low specific activity of W-188. Column chromatography generators with alumina or zirconium tungstate gel have been reported (Knapp et al., 1997; Boschi et al., 2014), but currently there is only a sole commercial supplier.

Widely used radionuclides

Technetium-99m

Technetium-99m is the most widely used radionuclide in nuclear medicine, in about 80% of all the diagnostic procedures, amounting to approximately 40 Million studies annually conducted throughout the world, earning it the name “Work-horse” of nuclear medicine. This is because of the excellent features of Tc-99m—such as, (a) $T_{1/2}$ of 6.02 h, decay by internal transition with emission of a single gamma ray of 140 keV energy that can be imaged with great sensitivity using the NaI(Tl) detectors, (b) availability from the Mo-99/Tc-99m generator system for repeated elution at very convenient time intervals (daughter RN Tc-99m grows to maximum level in about 24 h—most convenient for everyday elution and preparation of radiopharmaceuticals), (c) high production feasibility of Mo-99 in reactors through the fission route in very high yields, and (d) amenable chemistry of Tc-99m, making it feasible to label a large variety of molecules through complexation.

Technetium-99m, was discovered in 1939 (by Seaborg and Segre) soon after the discovery of the element technetium (the first man-made element, discovered in 1937, for which there are no naturally occurring stable or radioactive isotopes). The use and steep growth of Tc-99m started around the late 1960s when the Mo-99-Tc-99m generator was introduced in the market (Brookhaven National Lab developed the first Mo-99/Tc-99m generator in 1958—shown in Fig. 8, which was proven to be useful and commercialized in 1966) (Eckelman, 2009).

The period after introduction of a commercial Mo-99/Tc-99m generator witnessed an exponential growth in the development of new radiopharmaceuticals labeled with Tc-99m and their use in clinics. The Mo-99/Tc-99m generator yields ^{99m}Tc in the form of ^{99m}TcO₄[−] (pertechnetate) ion, which was the first product tested for its usefulness as a radiopharmaceutical. The monocharged anion behaved like an iodide ion and accumulated in the thyroid, enabling thyroid imaging. The ^{99m}TcO₄[−] pertechnetate ion was also shown to be useful in imaging the brain when the blood-brain-barrier is breached due to brain tumors. The versatile chemistry of Tc (with several oxidation states and amenability to complex with organic molecules) led to the development of a wide range of ^{99m}Tc based radiopharmaceuticals. The availability of gamma cameras, and later the SPECT cameras, gave a boost to the Tc-99m use.

The availability of the Mo-99/Tc-99m generator in adequate quantities throughout the year all around the world was a crucial factor in making Tc-99m the most used RN. In addition, with the availability of Tc-99m generators in the market during the 1970s, a wide range of Tc-99m tagged radiopharmaceuticals were developed for anatomical as well as functional imaging of the important organs. The development of numerous Tc-99m based radiopharmaceuticals to image all important diagnostic needs and making it possible for the hospital radio pharmacies to prepare these varied radiopharmaceuticals in the required quality (radiopharmaceutical purity, specific activity, biological purity—sterility and absence of pyrogens) by developing “cold-kits” (containing all the ingredients that can be used as per the instructions provided along with the Tc-99m eluted from the generator) have also been equally important for the versatile use of Tc-99m. In all, the entire supply chain involved in the use of Tc-99m (nuclear reactors, Mo-99 processors, Mo-99-Tc-99m generator producers, Cold kit producers, Hospital radiopharmacy) are important for uninterrupted use of Tc-99m based radiopharmaceuticals. (Note: The fragility of the medical radioisotope supply came to the fore during 2007–09, when the key medical radioisotope producing reactor NRU in Canada, which was supplying bulk of the global Mo-99, had a prolonged shutdown. The situation turned into a crisis when another major reactor in Netherlands also had an unplanned shut down. The global supply of Tc-99m generators was severely hit and triggered a global alarm for developing a more robust medical isotope supply strategy, which brought all the stake holders together to address the issue. The efforts through OECD is

Fig. 8 The first Tc-99m Generator (shown here without the shield) developed at the Brookhaven National Laboratory.

noteworthy in this context (OECD/NEA, 2019). Fortunately, the coordination among the key players in the supply chain of Mo-99 and Mo-99/Tc-99m generators and the entry of new/refurbished reactors and augmented capacities in existing reactors have now ensured the secure supply of the most important medical isotope, Tc-99m.)

^{99m}Tc based radiopharmaceuticals are currently available for imaging nearly all the important organs and functions of the vital organs (Table 1).

Fluorine-18

Fluorine-18, with a half-life of 110 min, is the most used PET nuclide. The high percentage (97%) of emission of positrons of low energy (0.638 MeV) enable high resolution images. The use of F-18 grew very quickly towards end of the last century, when the remarkable utility of the molecule F-18 labeled, 2-Deoxy-2-Fluoro-D-Glucose (F-18-FDG) in several ailments was established and PET cameras were available for use in clinics. While F-18-FDG is undoubtedly the most used PET tracer, several other F-18 labeled molecules are regularly used in diagnostic PET imaging (confer Table 2).

Radioiodines

I-127 is the only stable isotope of the element iodine. Of the numerous (37) radionuclides of iodine, I-131, I-124 and I-123 serve a valuable role in in-vivo nuclear medicine. These three are considered together, owing to some common strategies in their use. I-125, used in in vitro assays is not considered here. Iodine chemistry is very well understood and, hence, labeling a variety of biomolecules with radioiodine is well established.

I-131: Historically, I-131 has the longest period of widespread use and, hence, has a unique place in the history of nuclear medicine.

The first RN of iodine to be produced was ¹²⁸I (by Enrico Fermi) in 1934, and as the role of iodide in thyroid metabolism was established, it was used to study thyroid metabolism and disease starting in 1937. However, the discovery of I-131 in 1939 (by Glenn Seaborg) and its availability in the years that followed, made I-131 (with 8.06 days half-life, emission of several gamma rays and decay through beta emission,) a RN of choice for thyroid studies and for treatment of thyrotoxicosis (hyperthyroidism) and thyroid cancer. Radioiodine I-131 is, thus, the first radionuclide used in nuclear medicine—both for diagnosis and for therapy and is the first theranostic agent (Silberstein, 2012). The biochemical path of iodide ions causing it to concentrate in thyroid enables the use of I-131, in the form of inorganic iodide, to image thyroid as well as treat thyroid disorders. I-131

radioiodine has been advantageously and continuously used since 1940s. It was the first FDA approved radiopharmaceutical (1951) (SNMMI Historical Timeline).

I-131 is generally produced in reactors by the irradiation of a tellurium-130 target, which decays by beta emission to I-131. As the parent and daughter are different elements, separation of I-131 from a tellurium target yields high specific activity I-131, and most manufacturers use dry distillation method to separate radioiodine from the target (Shikata and Amano, 1973; IAEA-TECDOC-1340, 2003). The use of natural tellurium oxide target results in small amounts of other radioiodine impurities, most of which decay away due to short half-lives, barring I-129, which has a long half-life of 1.57×10^7 years. I-131 is also produced through the (n, fission) route using U-235 target material, similar to Tc-99m, since the fission yield for the mass numbers around 130 is also high, as for mass numbers around 100 (see earlier section on fission production of isotopes). With the wide availability from nuclear reactors, I-131 was tagged to different molecules for imaging vital organs. I-131 labeled human serum albumin for imaging blood pool in heart, I-131-Hippuran for kidney imaging, and I-131-rosebengal for liver imaging were used in the decades followed, until suitable Tc-99 based agents replaced them, as Tc-99m was far superior to I-131 for diagnostic imaging. An exceptional case is I-131 labeled meta-iodobenzyl guanidine (^{131}I -mIBG), which behaves like norepinephrine and, hence, accumulates in adrenergic neurons, making this agent suitable for imaging neural crest tumors including neuroblastomas.

Although I-131 is used for diagnostic imaging, it is not an ideal RN for imaging, as I-131 decays by beta emission and emits several gamma rays, rendering the image quality somewhat inferior for dosimetry. But, the beta particle with E_{max} 606 keV is suitable for therapy, and I-131 in the form of iodide is advantageously used in the treatment of thyrotoxicosis and thyroid cancer. Apart from thyroid related diseases, I-131 is used in the treatment of a few other malignancies, among which ^{131}I -mIBG in therapeutic doses has an unequivocal role in treatment of neuroblastomas, including in children. Several monoclonal antibodies (MAb) labeled with I-131 have been used in the treatment of specific cancers, among which I-131-anti CD-20 MAb tositumomab is an FDA approved radiopharmaceutical for treatment of non-Hodgkin's lymphoma (Kaminski et al., 2005). The use of I-131 labeled lipiodol for treatment of liver cancers (Kobayashi et al., 1986; Leung et al., 1994) are the few other established therapy applications of I-131.

I-124: ^{124}I , a positron emitter with a half-life of 4.17 d, is attractive for studies that require long times, as most other PET RNs are short lived. Targeting molecules such as antibodies, which have high molecular weight, take a much longer time (few days) than the small molecules for reaching the target. In such cases, it is desirable to have a RN that has comparable half-life, and I-124 fits the requirement very well (Cascini et al., 2014). While the positron emission allows PET imaging of I-124, the copious Auger electron emission can be used for therapy in the range of a few nanometers by using appropriate molecules to target the DNA of the cancer cells. Further, although the decay scheme of I-124 is complex, PET imaging with I-124 has better resolution than I-131 and allows accurate quantification for pre-therapy dosimetry calculations, making I-124 a valuable diagnostic RN as a theragnostic pair with I-131. Thus, I-124 is the only long-life positron emitter isotope of iodine that is amenable for both imaging and therapy as well as for ^{131}I dosimetry. However, although I-124 has the above-mentioned attractive features, the high energy of emitted positron with long range and a high proportion (77%) of decay via electron capture route pose challenges in obtaining high resolution images. I-124 is produced in cyclotrons using an enriched Te-124 target through (d, 2n), or more recently and preferably a (p, n) reaction (Lambrecht et al., 1988). Several I-124 labeled molecules include ^{124}I -MIBG, ^{124}I -IAZA, ^{124}I -IAZG, and ^{124}I -DRFIB. (Mahajan and Divgi, 2016).

Despite the several advantages of I-124, its use is currently limited.

I-123: Iodine-123, which decays by electron capture with a half-life of 13.3 h, is used in delineation of thyroid functional status and assessment of thyroid nodules as the 159 keV photon emission is ideally suited for SPECT imaging. But its short half-life limits the study to metabolic processes that are quick.

Gallium-68

Gallium-68, a positron emitter with 67.7 min half-life and 89% decay through positron emission, is currently a highly used PET RN, with a huge potential to grow further (Rösch, 2013). Its availability from a generator (see the previous section on Ge-68/Ga-68 generator), makes it an attractive PET RN for clinics that do not have access to a medical cyclotron. The $^{68}\text{Zn}(p,n)$ reaction is also used for direct production of Ga-68 when a suitable cyclotron is accessible. Ga-68 was explored as a diagnostic imaging RN to be derived from a Ge-68/Ga-68 generator long before F-18 was used (Gleason, 1960; Greene and Tucker, 1961; Yano and Anger, 1964). However, since in the past Ga-68 was eluted in the form of Ga-EDTA (Ethylene Diamine Tetra Acetic acid), which is a very strong complex, hard to replace with other ligands, its utility remained very limited to using the ^{68}Ga -EDTA complex as the tracer. Moreover, the steep growth in the use of Tc-99m based radiopharmaceuticals, and later of F-18 based molecules, resulted in Ga-68 taking a back seat, until a generator that provided cationic $^{68}\text{Ga}(\text{III})$ became available, ushering in a new phase of Ga-68 radiopharmaceuticals. Being a trivalent ion similar to $^{111}\text{In}(\text{III})$, Ga-68-DOTATATE was soon developed as a somatostatin receptor binding agent for PET imaging of neuroendocrine tumors, replacing In-111-DTPA-octreotide. The trivalent chemistry of Ga (III) enables its complexation with various suitable chelating agents, such as DOTA(1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) (Breeman et al., 2011). This is attractive since several therapeutic RNs such as Lu-177 are also trivalent and Ga-68-radiopharmaceutical can form a "Theranostic pair" with the same molecule labeled with a therapeutic RN. In recent years, $^{68}\text{Ga}(\text{III})$ -(HBED-CC)-PSMA-11 has gained a lot of attention as an agent for imaging prostate cancer lesions. Several ^{68}Ga labeled molecules are being explored as PET tracers, but are not covered here.

Radioisotopes of copper

Among the several copper radioisotopes, five of them, namely, Cu-64, Cu-67, Cu-62, Cu-61 and Cu-60 are considered suitable for use in nuclear medicine. But, of these, Cu-64 and Cu-67 have been explored well, Cu-62 to some extent, while the others have limitations (Boschi et al., 2018) and are not expanded here. Cu-62, which can be availed from a Zn-62/Cu-62 generator, has a short half-life of 9.74 min and the parent Zn-62 is also short lived with a half-life of 9.2 h. This makes the practical utility of Cu-62 very limited and is not detailed further here.

Copper-64: Cu-64 is a unique RN that decays by three different modes—positron (17.6%), electron capture (43.9%) and beta(−) decay (38.5%), accompanied by several Auger electrons. This makes it a suitable RN for PET imaging, as well as therapy—a theranostic RN, like I-131. A lot of work on Cu-64 has been reported in the past decade, especially as Cu-64 as Cu(II)chloride could target tumors (Boschi et al., 2018). Among various molecules labeled with Cu-64, Cu-64-ATSM has attracted attention for imaging tumor hypoxia. Cu-64 is generally produced in cyclotrons through the (p,n) reaction on Ni-64. Production via the (n, p) reaction on enriched Zn-64 target has also been reported.

Copper-67: Cu-67, a beta emitter with a half-life of 61.8 h, along with several imageable gamma rays, is another radionuclide that can be used as a theranostic RN, like I-131. But Cu-67 is predominantly proposed for use in therapy, with a theranostic pair Cu-64 for imaging.

Cu-67 is produced either through the (n, p) reaction on enriched Zn-67 in a reactor, or a (p,2n) reaction on enriched Zn-68 in a cyclotron. However, both routes have low cross sections and require high flux reactors or high energy cyclotrons. These pose limitations in the use of Cu-67.

Indium-111

In-111, a metallic radionuclide decaying by EC with a half-life of 2.8 days and emission of gamma rays of 171 and 247 keV, is a valuable RN for SPECT imaging. The amenable production in cyclotrons (through (p,n) or (p,2n) reaction on Cd-111 or Cd-112 target) and trivalent chemistry makes In-111 suitable for labeling biomolecules. Among the various molecules explored, In-111-Pentetreotide, for imaging neuroendocrine tumors expressing somatostatin receptors (Ivancevic et al., 1992), In-111 labeled leucocytes for infection imaging (Datz, 1994), and a few In-111 labeled MABs against tumor antigens (for imaging colorectal, ovarian and prostate cancers), were the most used. But, despite being a useful SPECT RN, the use of In-111 has reduced significantly after the wide availability of Ga-68.

Samarium-153

Sm-153, a beta emitter ($E_{\max}$ 0.81 MeV) with a small percentage of imageable gammas, half-life of 1.8 days, facile production in reactors through (n, γ) reaction on Sm-152, and convenient chemistry, render it a useful RN for therapy of medium sized lesions. Sm-153 labeled EDTMP has been used in pain palliation in skeletal metastases for many decades (Holmes, 1992). However, other products labeled with Sm-153 have yet to find wide use.

Lutetium-177

Lu-177, a beta emitter with a half-life of 6.64d, is an attractive therapeutic RN ($E\beta$ -max 0.5 MeV; imageable gammas) and can be produced amenably through the (n, γ) reaction on Lu-176 or the (n, p) reaction on Yb-176. Hence, the use of Lu-177 has grown exponentially in the past two decades. The (n, p) route yields 'no carrier added' (n.c.a.) grade high specific activity Lu-177, and is devoid of the long-lived Lu-177m (half-life 160.4 days), but the yields are far lesser than that for (n, γ) route (Dash et al., 2015). The major impact of Lu-177 has been due to the use of Lu-177-DOTATATE (a theranostic pair for In-111-Octreotide), for treatment of neuro endocrine tumors, though Lu-177-phosphonates were among the early radiopharmaceuticals to be used in palliative therapy. In recent times, Lu-177-PSMA-17 for treatment of prostate cancer has been used increasingly. The trivalent radiolanthanide chemistry is advantageously used to pair with trivalent diagnostic RNs such as Ga-67 and In-111 to develop Lu-177 based radiopharmaceuticals for therapy (Das and Banerjee, 2016).

Thallium-201

Tl-201, which decays through electron capture with a half-life of 73.1 h, was one of the early RNs used for myocardial perfusion imaging (Ritchie et al., 1977). Though considered the gold standard since Tl + 1 is analogous to K + 1, the use of Tl-201 had reduced considerably with the advent of Tc-99m-MIBI, primarily because Tc-99m from the Mo-99/Tc-99m generator is easy to access in comparison to Tl-201 produced in cyclotrons. But the use of Tl-201chloride returned in clinics after the Mo-99 supply shortages experienced during 2007–10 period and continues to be used (Pagnanelli and Basso, 2010).

Yttrium-90

Y-90, a pure beta-emitting RN (2.27 MeV $E_{\max}$) with a half-life of 64 h, availed from a Sr-90/Y-90 generator, is an ideal isotope for radionuclide therapy of large lesions (refer to the section on the Sr-90/Y-90 generator). The trivalent chemistry of yttrium makes it a suitable theranostic pair of Ga-68, and a good option for the treatment of large lesions for which Lu-177 is not the best choice. Yttrium-90 labeled monoclonal antibody ibritumomab tiuxetan (trade name Zevalin) is one of the two radiolabeled MABs for the treatment of non-Hodgkin's lymphoma. Apart from this product, use of Y-90 labeled microspheres (glass or resin) for selective internal radiation therapy (SIRT) of liver cancers (Salem and Thurston, 2006), Y-90 labeled peptide analogs of somatostatin in treatment of large neuroendocrine tumors (Otte et al., 1998; Bodei et al., 2004), and Y-90 phosphonates for palliative therapy in skeletal metastases have been reported with promising results. Use of Y-90 labeled particles for radiation synoviorthesis of large joints is also practiced in selected clinics (Chrapko et al., 2007).

Rhenium-188

Re-188 is another ideal therapeutic RN, as it emits high energy beta particles, ($E_{\max}$ 2.12 MeV) along with a low percentage of gamma emission (15% of 155 keV). It can be availed from a generator (refer W-188/Re-188 generator) and chemically belongs to the same group as Tc-99m, making it a theranostic pair of Tc-99m. However, its use depends on the generator availability, as the direct neutron activation production of Re-188 by irradiating enriched Re-187 has limitations of RN impurities and low yields. Re-188 labeled lipiodol for treatment of hepatocellular carcinoma (Jeong et al., 2001) is the most reported application, while use of Re-188 phosphonates for palliative treatment of skeletal metastases (Lepareur et al., 2019) and Re-188 particulates in radiation synoviorthesis of large joints are also practiced in limited centers (Knapp and Dash, 2016).

$^{227}\text{Ac}/^{223}\text{Ra}$ and $^{225}\text{Ac}/^{213}\text{Bi}$

Alpha radiation with high LET is attractive for therapy when the RN can be lodged close to the cancer cells. Among the various alpha emitters explored for therapy, Ra-223 and Ac-225 have shown promising results (Morgenstern et al., 2020; Kratochwil et al., 2020) and are detailed below:

Ra-223: Radium-223, in the form of radium chloride, is the first targeted alpha therapy radiopharmaceutical approved for clinical use for the palliative treatment of castration-resistant prostate cancer (CRPC) patients with symptomatic bone metastases (Brito and Etchebehere, 2020). Radium-223 is selectively accumulated in the bone, specifically in areas of high bone turnover, by forming complexes with the mineral hydroxyapatite (the inorganic matrix of the bone). The alpha radiation generated during the radioactive decay of radium-223 produces a palliative anti-tumor effect on the bone metastases. The treatment has been shown to be useful in life span extension and pain palliation in patients. Ra-223 chloride was the first commercial alpha therapy product. However, the radiolabeled phosphonates (Sm-153; Lu-177; Re-188) and ^{89}Sr -chloride, which have been used for the same purpose, have not been replaced by Ra-223 chloride—both due to availability and affordability.

Ac 225: The initial success of ^{223}Ra chloride led to the exploration of other alpha emitting RNs for therapy—some of which had been studied in the past, but abandoned due to practical difficulties in obtaining the RN as well as targeting. ^{225}Ac , with a half-life of 10 days, emits alpha particles and has a sequential decay pattern resulting in several alpha particles (as shown below Table 5). ^{225}Ac sequentially decays with α particle emissions to ^{221}Fr (4.9 min); ^{217}At (32.3 ms) and ^{213}Bi (46 min), and all the four α particles aid in therapy. But, such high energy alpha emission could result in recoil energy that is much higher than the energy of the chemical bond of the nuclide, and this could lead to the release of a daughter nuclide from the radiopharmaceutical molecule that is usually a conjugate of the target specific vector with a chelating moiety that holds the radionuclide. In such a case, the radionuclide will no longer be carried to the target, and could lead to normal tissue toxicity. For example, if ^{221}Fr (4.9 min), the decay of the product of ^{225}Ac , gets detached from the target specific molecule (it is similar to potassium, same group in periodic table and analog), it can be taken up in myocardium, which is not desirable. To avoid such problems, an option is to consider using ^{213}Bi , which results after four successive alpha emissions from ^{225}Ac .

The current research on ^{225}Ac is also focused on production of ^{225}Ac , since the current supplies from ^{229}Th are limited (60–70 GBq/year) and can be used to treat only a few thousand patients. ^{229}Th is obtained from the decay of ^{233}U , availed from the old legacy stocks existing in a few countries in the world (US-DOE Isotope Program; Russian Federation-Institute of Physics and Power Engineering, Rosatom; Europe- European Commission-Joint Research Centre and Canada-Canadian Nuclear Lab). Currently, the methods for production of ^{225}Ac that have shown some promise are (i) bombarding high energy protons on thorium targets in high energy proton LINACs (^{232}Th (p, spallation)), (ii) ^{226}Ra (p,2n) in a high energy accelerator, (iii) photon induced (γ , n) reaction on ^{226}Ra in electron accelerators where in the ^{226}Ra obtained decays to ^{225}Ac , and (iv) (n,2n) reaction on ^{226}Ra using high energy neutrons. All these methods have inherent challenges related to low yields, radionuclide impurities, and handling radioactive gas (^{222}Rn), which must be overcome to make them practical and sustainable.

^{213}Bi has also been widely studied as a therapeutic radionuclide and is availed from ^{225}Ac , in the form of a generator. But ^{225}Ac has the therapeutic advantage of alpha cascade and a much longer half-life (10 days) compared to that of ^{213}Bi (46 min), which is favorable for bio-distribution within the body and is, hence, avidly pursued for targeted therapy (Scheinberg and McDevitt, 2011). The short half-life of ^{213}Bi will also be a constraint in preparing clinical doses of ^{213}Bi radiopharmaceuticals, although generator production has logistic advantages.

Several other RNs such as Zr-89 (Zhang et al., 2011), Sc-44 (Rösch, 2012), Ti-45 (Chaple and Lapi, 2018) have been reported with promising results or high potential for use and are yet to be used in regular clinical practice. Hence, they are not detailed here. Other RNs, such as Rb-82, are used regularly for specific purpose and have already been detailed in the earlier section on generators.

As mentioned earlier, the concept of “Thera(g)nostics” is increasingly used for planning therapy that is personalized for better efficiency. Therapeutic radionuclides with imageable gamma emission have been used for imaging followed by therapy since long. I-131 iodide is the oldest in this context. Among the several “theragnostic” pairs listed in Table 4, a few (Ga-68 and Lu-177/Ac-225; I-123 and I-131) are commonly used.

Conclusion

Nuclear medicine is a unique modality, enabling accurate diagnosis, therapy as well as monitoring patients post treatment in several major diseases and, thus, significantly contributes to human welfare and longevity. Radionuclides, a vital part of the radiopharmaceuticals used in nuclear medicine, have constantly evolved. A wide variety of radionuclides are currently available for imaging, making it possible to obtain unequivocal diagnostic information as well as for efficient targeted therapy.

Glossary

Those in italics are defined in more detail in Chapter 3A (Venkatesh and Kang, 2021).

Alpha rays *Alpha particles, identical to a helium nucleus.*

Amyloid plaques A pathological feature of Alzheimer's disease, which is aggregates of misfolded proteins that form in the spaces between nerve cells.

Becquerel (Bq) Standard International (SI) derived unit of radioactivity, equal to one disintegration per second (1 dps). The non-SI unit of radioactivity "curie" (denoted as Ci, which is the radioactivity in 1 gram of radium) is related to Bq as $1 \text{ Ci} = 3.7 \times 10^{10} \text{ Bq}$. Becquerel is an extremely small amount of radioactivity and in practice, the amounts of radioactivity are several orders of magnitude higher. They are represented as kilo Bq (kBq), mega Bq (MBq), giga Bq (GBq), tera Bq (TBq), etc.

Beta particles *Particles with a mass of electrons; Most have a negative charge and are called negatrons; Those with a positive charge are called positrons.*

Biological half-life Molecules that have biological action (such as drugs, radiopharmaceuticals, etc.) get depleted from the body (either due to excretion or conversion to another molecule or disintegration due to instability) with time. The time taken for the original amount of the active component to decrease to half its original amount is known as biological half-life. In the case of radiopharmaceuticals, both the physical half-life of the radionuclide as well as the biological half-life of the biomolecule are applicable.

C-11-PIB Carbon-11-labeled Pittsburgh Compound B, (C-11 PIB), is a radiotracer used with positron emission tomography (PET) scanning to image the build-up of beta-amyloid plaques in the brain, which are associated with Alzheimer's disease.

CAD/IHE Coronary Artery disease/Ischemic Heart disease—Heart diseases could be due to different causes (such as malfunctioning valves or shunt), among which the most common is due to abnormal (often blockage) coronary artery leading to poor blood flow and affected regions (ischemia) in the heart muscle. Heart diseases due to defective coronary artery leading to ischemia of heart muscles are called "Coronary Artery Disease or Ischemic Heart Disease." A diagnostic imaging test to visualize the coronary arteries and the blood flow to heart muscles helps the cardiologist treat the patient in an appropriate way.

Castration resistant prostate cancer (CRPC) Prostate cancer is one of the common cancers in males. As prostate cancers are often driven by the male sex hormones androgens, the first line of treatment for prostate cancer patients is androgen deprivation therapy, either through surgery or with drugs. However, in some cases, the cancer continues to grow and at times metastasize despite hormone therapy and irrespective of the levels of androgen. This disease state is referred to as castration-resistant prostate cancer (CRPC).

Chelate Chelate is a compound wherein a metal ion is attached through two or more coordination bonds to atoms of a ligand, which is usually an organic molecule. The word chelation is derived from *chēlē*, meaning "claw" in Greek. In a chelate, the central atom is attached with one or more ligands called chelators like the claws of a lobster.

Chemisorption A kind of adsorption that involves a chemical reaction between the surface and the adsorbate.

*Retired.

Cisternography An imaging test to diagnose a cerebrospinal fluid (CSF) leak or identify blockages in the CSF pathway. By injecting a small amount of radioactivity into the spinal fluid via lumbar puncture, the flow of the spinal fluid from the spine into the brain can be evaluated.

Decay constant (λ) *The probability of transmutation of a radionuclide.*

Diagnostic nuclear medicine *The branch of nuclear medicine used for diagnostic purposes.*

Dyspnea Shortness of breath, a feeling of not being able to breathe well enough.

Ejection fraction (EF) *The fraction of blood pumped out of the heart every time the heart contracts.*

Electrocardiogram (ECG) *A test done to measure the electrical activity of the heartbeat.*

Electron capture (EC) *A mode of transmutation wherein an orbital electron is captured, causing a proton in the nucleus to become a neutron.*

Etiology The study of causation or origination.

Gamma rays *Photons with an electromagnetic radiation.*

Half-life *The time taken for one-half of the original decaying radionuclide to transmute into its daughter product.*

Hydrocephalus An abnormal accumulation of cerebrospinal fluid (CSF) within cavities in the brain called ventricles.

Ictal phase The middle stage of a seizure.

In vitro *In glass or outside the body.*

In vivo *Inside the body.*

Interictal phase The period between seizures, or convulsions, that are characteristic of an epilepsy disorder.

Linear energy transfer (LET) *The transfer of energy through a medium by radiation (such as alpha or beta rays).*

Lipophilicity The ability of a chemical compound to dissolve in fats, oils, lipids, and non-polar solvents.

Molecular imaging *Signaling via a bi-molecular action of the tracer used.*

Monoclonal antibodies (MAB) *Antibodies derived from the same "clone," having identical characteristics and behavior.*

Neuroblastoma A cancer that develops from immature nerve cells. It most frequently starts from one of the adrenal glands but can also develop in the neck, chest, abdomen, or spine. It is the most common cancer in babies and the third-most common cancer in children after leukemia and brain cancer.

Norepinephrine secreting cell Norepinephrine is a hormone and neurotransmitter, excreted during situations of stress or danger, in the so-called fight-or-flight response. Norepinephrine secreting cells are in the sympathetic ganglia near the spinal cord or in the abdomen and the adrenal glands.

Osteomyelitis An infection of bone.

Paraganglioma A rare neuroendocrine (cells that secrete hormones in response to signals from nervous system) neoplasm (neoplasm is abnormal growth of cells/tissues—could be cancerous or non-cancerous) that may develop at various body sites (including the head, neck, thorax and abdomen). When the same type of tumor is found in the adrenal gland, they are referred to as a pheochromocytoma.

Peptide receptor radionuclide therapy (PRRT) *A therapy of cancers that overexpress specific peptides on cell surfaces using radiolabeled peptides that bind specifically to these receptors.*

Phagocytosis The process by which a cell uses its plasma membrane to engulf a large particle. It is a main mechanism of the innate immune defense.

Pheochromocytoma A rare, chromaffin cell tumor of the adrenal medulla. It results in the release of too much epinephrine and norepinephrine—hormones that control heart rate, metabolism, and blood pressure. This can lead to high blood pressure.

Positron emission tomography (PET) *A tracer technology based on using positrons to isolate a tomographic image.*

Positrons *Beta particles with a positive charge.*

Pyelonephritis Inflammation of the kidney, typically due to a bacterial infection.

Radioembolization A cancer treatment in which radioactive particles are delivered to a tumor through the bloodstream.

Radiolabeled diagnosis (RID) *A nuclear medicine procedure wherein a radiolabeled antibody is used for diagnostic purposes.*

Radiolabeled therapy (RIT) *A nuclear medicine procedure wherein a radiolabeled antibody is used for therapeutic purposes.*

Radionuclide *An unstable isotope that decays into a more stable isotope via radioactive emission.*

Radiopharmaceuticals *A drug formulation containing radioactivity.*

Radiosynoviorthesis A treatment for the restoration (orthesis) of the synovium (the connective tissue that lines the cavities of joints and makes synovial fluid, which lubricates the joints) by local administration of radioactive agents.

Red blood corpuscles (RBC) *Red blood cells that carry oxygen throughout the body.*

Reticuloendothelial system A part of the immune system that consists of the phagocytic (eating) cells located in reticular connective tissue, such as lymph nodes, the liver, and the spleen. The phagocytic cells, such as macrophages (white blood cell that engulfs and digests cell debris, foreign substances, microbes, etc.) and endothelial cells (cells lining the interior surface of blood vessels), clear macromolecules and nanoparticles from the blood circulation.

Single photon emission computed tomography (SPECT) *A tracer technology based on a gamma emitter to isolate a tomographic image.*

Sodium iodide symporter (NIS) NIS is a membrane protein that aids in the transport of *iodide* ions (and sodium ions) into thyroid follicular cells. It plays a crucial role in *iodine* metabolism and thyroid regulation.

Somatostatin receptor imaging A molecular imaging system that targets somatostatin receptors, which are over-expressed in neuroendocrine tumors.

Tachypnea A respiration rate greater than normal, resulting in abnormally rapid breathing.

Tau protein A microtubule-associated protein in neurons. Aberrant assembly of tau into insoluble aggregates is accompanied by synaptic dysfunction and neural cell death in a range of neurodegenerative disorders, such as Alzheimer's disease, Parkinson's disease, etc.

Therapeutic nuclear medicine *The branch of nuclear medicine in which radiopharmaceuticals are labeled with radionuclides for therapeutic purposes.*

Trans arterial radioembolization (TARE) A catheter-based liver-directed therapy that involves injection of micron-sized embolic (blocking caused by pieces of material inside a blood vessel) particles loaded with a radioisotope by use of percutaneous transarterial techniques.

Introduction

Nuclear medicine (NM) is the specialty in which a radiolabeled substance known as a *radiopharmaceutical* is administered into the patient (also referred as “in vivo” administration), either for diagnostic or for therapeutic purpose. While the “traceability” of radioisotopes allows the imaging of radiopharmaceuticals, which in turn can provide information about an organ (size, shape, abnormalities, functioning), the deleterious nature of high-energy, high dose-rate radiation is used in therapy to destroy diseased cells, such as cancer cells. Since the behavior of the radiopharmaceuticals inside the body is governed by the biochemistry of the molecule and the biochemical functioning of the concerned body organs, nuclear medicine studies provide unique functional information unlike several other imaging modalities. Thus, nuclear medicine imaging is also referred to as functional imaging or molecular imaging (Venkatesh and Kang, 2021).

Currently, nuclear medicine offers diagnostic procedures to image all the important organs and functioning of vital organs and therapeutic options for several disease conditions. Nuclear medicine imaging enables anatomical as well as functional (characterization and measurement of biological processes at molecular/cellular/whole organ level) evaluation. It has evolved as an important branch of medicine providing unique and unequivocal support for patient management, especially for patients with cancers or heart diseases.

Radiopharmaceuticals

Radiopharmaceuticals are radiolabeled molecules administered into the patient, most often through intravenous route and in some cases orally; hence, termed “in vivo” radiopharmaceuticals. The basis of the use of radiopharmaceuticals is the unique biological behavior of the radiopharmaceutical inside the body and localization in target organs/lesions. This enables either diagnostic imaging to look at various organs and their functioning or therapeutic dose delivery to diseased tissues. Radiopharmaceuticals have two components; namely, the radionuclide and the molecule that is radiolabeled. The choice of the radionuclide will depend on the intended use—either diagnosis or therapy. The molecule used for radiolabeling will determine the fate of the radiopharmaceutical when it is administered into the body.

At the beginning of the practice of nuclear medicine, the radiopharmaceuticals were often simple chemicals in their inorganic form, which had the desired biological behavior inside the body. This could be considered as the first-generation radiopharmaceuticals, and Iodine-131 in the form of iodide is an excellent example. Iodide ions, when ingested, get absorbed in the blood stream and quickly concentrate in the thyroid gland. This attribute was used advantageously to image the thyroid as well as to treat thyroid cancers. A few other radiopharmaceuticals, which are simple inorganic molecules currently in use, are Tc-99 m as pertechnetate ($^{99m}\text{TcO}_4^-$, used in thyroid imaging), Tl-201 as Thallous chloride ($^{201}\text{TlCl}$, used in myocardial perfusion (blood flow to the heart muscle) imaging/imaging the flow of blood in the heart), and Ra-223 as radium chloride ($^{223}\text{RaCl}_2$, used in palliation of pain from skeletal metastases).

However, not all organs could be so easily targeted using a simple molecule. The next range of radiopharmaceuticals were radiolabeled molecules consciously designed to have desired charge, size, lipophilicity (affinity to fatty molecules), etc. to target the organ/tissue of focus. Here, the knowledge about the biochemical functioning of the organ guided the choice of molecules. For example, it was well known that the liver processes lipophilic (fatty) molecules and kidneys process hydrophilic (water soluble) molecules. Such insight formed the basis to design radiopharmaceuticals that can be used to image these organs. The knowledge that potassium cation (K^+) binds to heart muscles (myocardium) formed the basis for the use of Tl-201 as a Tl^+ ion and cationic complexes of Tc-99 m for imaging myocardial perfusion. In a few cases such as spleen, lungs and bone marrow, which have a reticuloendothelial system, physical trapping has been used to target and localize the radiopharmaceuticals.

As the understanding of the biochemistry expanded, and with advances in molecular targeting of various organs/disease conditions, a huge variety biochemicals and biologically active molecules have been radiolabeled and used as radiopharmaceuticals. An outstanding example is the use of radiolabeled glucose to image metabolic activity, which has proved to be an excellent way to deduce information on active tumors/cancers—since they have metabolic rates far higher than normal tissues. Biologically active specific targeting molecules such as peptides and antibodies have had a great impact on the management of cancers and have also influenced the field of radiopharmaceuticals. Radiolabeled peptides and antibodies that can bind to cancer cells with great specificity are now used widely, and consequently, the terms radio immuno diagnosis (RID), radio immuno therapy (RIT), and peptide receptor radionuclide therapy (PRRT) have been coined.

One way to classify the targeting mechanism of the current radiopharmaceuticals is as follows:

- a. Active/metabolic transport (example: I-131 used in thyroid imaging/cancer therapy).
- b. Phagocytosis/entrapment of particles (example: Tc-99 m sulfur colloid for liver/spleen imaging).
- c. Entrapment due to size/blockade (example: Tc-99 m serum albumin macroaggregates for lung perfusion imaging).
- d. Diffusion across cell membranes (example: F-18 fluoride in bone imaging).
- e. Compartmental localization- the radiopharmaceutical distributed in an enclosed volume such as the blood pool, GI tract, lung airways, lymphatic channels, urinary tract, etc. (example: Xe-133 gas in lung perfusion imaging).
- f. Chemisorption (example: binding of radiolabeled phosphates to the bone).
- g. Ion exchange (example: binding of calcium⁺² analogs such as Sr⁺² to the bone).
- h. Cell sequestration—as in spleen, use of heat-treated RBC labeled with Tc-99 m.
- i. Immune binding—specific binding of the antibody and antigen used for targeting (example: radiolabeled monoclonal antibodies in RIT and RID).
- j. Receptor binding (example: use of peptide analogs to target tissues/lesions expressing specific receptors—such as In-111 or Tc-99 m Octreotide to target somatostatin receptor expressing neuro endocrine cancers).

A major difference between the “radiopharmaceuticals” and regular pharmaceuticals is in the amount of the targeting molecule administered. The amount of the biomolecule in radiopharmaceuticals is in nanomolar quantities, which is several magnitudes lower than the regular pharmaceuticals. The radionuclide component is the one that provides the information (in diagnostics) or causes cell damage (in therapy). The role of the bio-active molecule is primarily to carry the radionuclide to the target tissue. Hence, radiopharmaceuticals are not expected to cause physiological effects when administered.

An important aspect of radiopharmaceuticals is compliance with regulatory requirements for administration into patients (IAEA, 2018; Saha, 2018). These quality control measures are extremely important and are crucial for radiopharmaceutical preparation and supply. The quality control (QC) tests are aimed at testing and ensuring the quality from physical, chemical and biological angles. In general, the QC tests include testing for (i) radionuclidic purity to ensure that the levels of unwanted radionuclides that can give undesired radiation dose are below the allowed levels, (ii) radiochemical purity to ensure that the radionuclide is present in the desired chemical form and that the unwanted radiochemical impurities are below the allowed limits, (iii) sterility of the product, (iv) (in injectables) absence of pyrogens (substances that cause fever), (v) chemical purity to ensure that the levels of chemicals used in preparation of the radiopharmaceuticals are below the allowed limits, and (vi) the parameters such as pH, molarity, etc. are as desired as given in the product manual.

Tc-99 m Based Radiopharmaceuticals: Radiopharmaceuticals tagged with ^{99m}Tc and ¹⁸F are the most used. ^{99m}Tc based radiopharmaceuticals, which are currently available for imaging nearly all the important organs and functions of the vital organs, are listed in **Table 1**.

Technetium does not occur naturally and, hence, Tc-99 m is a foreign entity to all molecules. The versatile chemistry and multiple oxidation states of Tc are great advantages for radiolabeling molecules with Tc-99 m. Nevertheless, it is often a challenge to radiolabel a biomolecule with Tc-99 m to get a radiolabeled molecule that retains its integrity after administration into the body. Tc-99 m, a radiometal, is best incorporated into a molecule through complexation using suitable chelating atoms/moieties. In the case of Tc (a soft metal) oxygen, nitrogen, or sulfur are good chelating atoms that can form strong complexes. The radiometal center with the surrounding chelating groups is of significant size and could influence the in-vivo behavior of the molecule, especially if the molecule is small. Tc-99 m radiopharmaceuticals could be categorized as follows:

- 1) Radiopharmaceuticals that are bare ^{99m}Tc-complexes owe their specificity to the whole complex and not the chelating molecule alone. Here, Tc-99 m is an important component of the biological action. These are “radionuclide essential” radiopharmaceuticals. The brain imaging agents ^{99m}Tc-ECD (ethyl cysteinate dimmer), ^{99m}Tc-hexakis methoxy isobutyl isonitrile (^{99m}Tc-MIBI), ^{99m}Tc-HMPAO (d, l hexa methyl propylene amine oxime), and several other small complexes of Tc-99 m in the above table, belong to the RN essential radiopharmaceutical category.
- 2) In the case of physical particles, such as colloids labeled with Tc-99 m, the mechanism of radiopharmaceutical action is based on the physical size. Here, the labeling is not specific, and the radiopharmaceutical is not “radionuclide essential” type. An example is sulfur colloid labeled with Tc-99 m.
- 3) Most large molecules, such as proteins, are radiolabeled using chelating moiety either already present in the molecule or specifically attached for complexation of the RN. Such specifically attached chelating moiety is known as “bifunctional chelating agent” (BFCA), as this moiety is linked to the bioactive molecule on one end and holds on (chelates) the RN at the other. These are also “radionuclide non-essential” radiopharmaceuticals. Peptide and antibodies labeled with Tc-99 m belong to this category.

Table 1 Tc-99 m based radiopharmaceuticals.

Radiopharmaceutical	Use
^{99m}Tc -pertechnetate	Thyroid and salivary gland imaging
^{99m}Tc -hexakis methoxy isobutyl isonitrile (^{99m}Tc -MIBI);	Myocardial perfusion imaging
^{99m}Tc -ethoxy ethyl 3,12-dioxo-6,9-diphosphate tetradecane (^{99m}Tc -tetrofosmin)	
^{99m}Tc -pyrophosphate	Myocardial infarct (tissue that is damaged and not functional due to lack of blood supply) imaging
^{99m}Tc -HSA microspheres	Lung perfusion studies
^{99m}Tc -aerosols	Lung ventilation studies
^{99m}Tc -phytate	Liver scintigraphy/imaging
^{99m}Tc -mebrofenin	Hepatobiliary tract scintigraphy (imaging of the liver, gallbladder and the ducts)
^{99m}Tc -diethylene triamine pentaacetic acid (^{99m}Tc -DTPA)	Renal function—glomerular (a network of small blood vessels capillaries, located at the beginning of urine flow in the kidney) filtration rate; renal scintigraphy
^{99m}Tc -glucoheptonate (^{99m}Tc -GHA);	
^{99m}Tc (III)-dimercaptosuccinic acid (^{99m}Tc (III)-DMSA)	Renal tubular function imaging
^{99m}Tc -mercaptoacetyl triglycine (^{99m}Tc -MAG3);	
^{99m}Tc -ethylene L,L, dicysteine (^{99m}Tc -EC)	
^{99m}Tc -L,L,ethyl dicysteinate dimer (^{99m}Tc -ECD);	Brain perfusion imaging
^{99m}Tc -d,l-hexamethylene propylene amine oxime (^{99m}Tc -HMPAO)	
^{99m}Tc -TRODAT-1 (a tropane derivative)	Dopamine transporter imaging in brain (in Parkinson's disease)
^{99m}Tc -methylene diphosphonate (^{99m}Tc -MDP)	Skeletal imaging; imaging skeletal metastases, osteomyelitis, arthritis, fractures, bone metabolism, etc.
^{99m}Tc -hydroxy ethylene diphosphonate (^{99m}Tc -HEDP)	
^{99m}Tc -hydroxy methylene diphosphonate (^{99m}Tc -HMDP)	
Tin-pyrophosphate followed by $^{99m}\text{TcO}_4^-$	In vivo RBC labeling for cardiac blood pool studies, etc.
^{99m}Tc -leucocytes	Infection imaging
^{99m}Tc -HSA nanocolloid	Sentinel node imaging; lymphoscintigraphy and bone marrow imaging
^{99m}Tc -sulfur colloid	Lymphoscintigraphy and bone marrow imaging
^{99m}Tc (V)-dimercapto succinic acid (^{99m}Tc (V)-DMSA)	Tumor imaging- medullary carcinoma
^{99m}Tc -HYNIC-[D-Phe1, Tyr3-Octreotide] (^{99m}Tc -Tektrotyd)	Imaging somatostatin receptor expressing neuro endocrine tumors

F-18 Based Radiopharmaceuticals: The growth in the use of F-18 was phenomenal owing to the remarkable utility of F-18-FDG in several ailments and the excellent PET images, earning it the name “Molecule of the Millennium.” F-18-FDG, in which the hydroxyl group in glucose is replaced with a F-18 atom, was originally developed to study the glucose metabolism in brain (Anderson et al., 2019). Although ^{18}F -FDG is taken up by cells, just as glucose, the lack of a 2-hydroxyl group in ^{18}F -FDG makes it different from glucose in the next steps of metabolism. Consequently, after the first step of phosphorylation, the F-18-FDG-6-phosphate formed is trapped in the cell. Thus, ^{18}F -FDG was established as a tracer to image glucose metabolism, which was used in brain/neurological research to understand disorders such as Alzheimer's disease, epilepsy, drug addiction, etc.

Towards end of the 1970s and beginning of the 1980s, the use of ^{18}F -FDG soon expanded to reveal information about the functioning of different tissues/organs, including myocardial metabolism and tumor metabolism. With the development of a radiolabeling method to obtain ^{18}F -FDG in high yields around mid-1980s, its use in cancer management grew steeply. Since cancer cells divide in an uncontrolled manner and have a high demand for glucose, the cancerous lesions light up clearly in ^{18}F -FDG imaging, much before any anatomical change is noticed. Currently, millions of ^{18}F -FDG scans are performed annually in cancer patients for diagnosis, treatment monitoring, and also for anti-cancer drug evaluation.

While F-18-FDG is the most used PET tracer currently, the attractive features of PET imaging and the availability of F-18 from several medical cyclotrons led to the quest for more F-18 labeled PET tracers for use in diagnosis of other conditions. Currently, there are some F-18 based PET radiopharmaceuticals used in clinics, as listed in Table 2, along with several F-18 based radiolabeled molecules in research that are not listed here.

Table 2 F-18 based radiopharmaceuticals.

Product	Use
^{18}F -fluoro deoxy glucose (^{18}F -FDG)	Glucose metabolism-widely used in oncology for imaging tumors
^{18}F -fluoro DOPA (^{18}F -DOPA)	Brain imaging for diagnosis of Parkinsonism and Alzheimer's, whole body imaging for neuroendocrine tumors
^{18}F -choline	Prostate cancers, parathyroid adenoma
^{18}F -fluoride	Skeletal imaging (for tumors; bone metastases)
3'-deoxy-3'-[^{18}F]fluorothymidine (^{18}F]FLT)	Thymidine metabolism-used in imaging cell proliferation—especially in brain tumors, sarcomas
O-(2-[^{18}F]fluoroethyl)-L-tyrosine (^{18}F FET)	Tumor imaging (amino acid metabolism)
^{18}F -fluoromisonidazole (^{18}F -FMISO)	Hypoxia imaging; oncology

The other commonly used radiopharmaceuticals are detailed further in the later section on the radiopharmaceuticals used in targeting specific organs.

Diagnostic nuclear medicine

Diagnostic imaging is aimed at obtaining information about (i) shape and size of organs—such as thyroid, liver, etc.; (ii) functioning of organs—such as heart, kidneys, liver, lungs, brain, etc.; and (iii) shape, size and location of tumors/nodules—in various cancers, etc. Such imaging is used to diagnose the diseases/cause for the diseases and follow up response to treatment. In addition, diagnostic imaging is also used to study the fate of the molecule of interest when administered into the body in research-oriented studies, such as drug research (Venkatesh and Korde, 2021).

In routine clinical practice, diagnostic imaging is predominantly used in cardiology and oncology, and to a significant extent in neurology to determine the functioning of vital organs such as liver and kidneys. In the earlier sections of this article, while describing the important radionuclides used in nuclear medicine, a significant amount of information on some of these RNs in diagnostic NM has been given. In the present section, the focus is on the disease conditions and the use of different radiopharmaceuticals in diagnosis. The important aspects in the imaging of major organs/systems/diseases are briefly described below.

Cardiovascular system—heart

The heart, one of the most vital organs, is assessed for its functioning utilizing several parameters for diagnosis of heart diseases, all of which can be estimated using nuclear medicine imaging and, hence, nuclear cardiology has an important role in management of cardiac patients (Taillefer and Harel, 2018; Manabe et al., 2018). Coronary artery disease (CAD), also called ischemic heart disease, is a major health concern globally. Nuclear medicine imaging aids in diagnosis/confirmation of CAD, stratification of risk, and treatment response assessment. NM imaging is highly valuable as a prognostic tool in asymptomatic patients at high risk of CAD, such as diabetes patients. Another important value of nuclear medicine imaging is in identifying patients with an extremely low risk of cardiac events, even if an invasive test such as coronary angiography suggests CAD. In addition, in all cases where stress ECG test findings are equivocal or inconclusive, nuclear medicine imaging is useful to decide if the patient needs to go for an invasive coronary angioplasty test. Thus, the negative predictive value of nuclear medicine scan can save unnecessary investigations and save resources.

Myocardial perfusion imaging (imaging blood flow in the heart) is used to delineate areas in the myocardium that are damaged (ischemic—meaning tissue that is still viable, or infarcted—meaning tissue that is dead and not viable) from normal healthy parts by imaging the heart under normal conditions and stressed (under exercise or induced through drug) conditions (Iskandrian et al., 2018). This is a valuable non-invasive evidence-based tool for cardiac care management. The radiopharmaceuticals used in perfusion imaging are $^{201}\text{TlCl}$, $^{99\text{m}}\text{Tc}$ -sestamibi, $^{99\text{m}}\text{Tc}$ -tetrofosmin, $^{82}\text{RbCl}$, and $^{13}\text{NH}_3$. $^{201}\text{TlCl}$, where the Tl^+ ion mimics K^+ ion was the first cardiac perfusion imaging agent introduced in 1973 and soon after used in clinics regularly. $^{201}\text{TlCl}$ is considered the gold standard in myocardial perfusion imaging due to the superior performance features (high: $\sim 85\%$ myocardial extraction, good: 3–4% uptake in myocardial tissues, and slow wash out from viable but ischemic tissues) that allows a single injection of the radiopharmaceutical—unlike the other radiopharmaceuticals used in perfusion imaging.

Although the corresponding features for $^{99\text{m}}\text{Tc}$ radiopharmaceuticals are not as good, the image quality is better. Accessing $^{99\text{m}}\text{Tc}$ is much easier and cheaper than ^{201}Tl , and, hence, currently most clinics use $^{99\text{m}}\text{Tc}$ based radiopharmaceuticals for myocardial perfusion imaging. The efforts to develop an ideal myocardial perfusion imaging $^{99\text{m}}\text{Tc}$ -based radiopharmaceutical were aimed at designing a cationic complex of $^{99\text{m}}\text{Tc}$ that will mimic K^+ ion (just as $^{201}\text{Tl}^+$) and be taken up by the myocardium. $^{99\text{m}}\text{Tc}$ -sestamibi ($\text{Tc}(\text{I})$ hexakis isonitrile mono-cationic complex), was the first successful molecule that came to market in 1986, followed by another monocationic complex $^{99\text{m}}\text{Tc}$ -tetrofosmin ($\text{Tc}(\text{V})$ [6,9-bis(2-ethoxyethyl)-3,12-dioxo-6,9-diphosphatetradecane]). Both these $^{99\text{m}}\text{Tc}$ radiopharmaceuticals need to be injected twice in patients to get the perfusion images at rest and stress (Fig. 1).

A few other complexes of $^{99\text{m}}\text{Tc}$ that were promising for myocardial perfusion imaging did not make it to the clinics. One example is $^{99\text{m}}\text{Tc}$ -teboroxime, a neutral complex of $^{99\text{m}}\text{Tc}$, which had the best performance with respect to myocardial extraction (higher than $^{201}\text{TlCl}$ and far better than $^{99\text{m}}\text{Tc}$ -sestamibi and $^{99\text{m}}\text{Tc}$ -tetrofosmin), but was too quickly washed out making it difficult to image. However, with advances in imaging systems that can acquire images very quickly (within 5 min—ultrafast systems), $^{99\text{m}}\text{Tc}$ -teboroxime could find a place in regular clinical use for myocardial imaging in the future.

With the advent of clinical PET imaging in the 1990s, $^{82}\text{Rb}^+$ and $^{13}\text{NH}_3$ were used in myocardial perfusion imaging. PET images have superior resolution of the “defective” regions and better quantification features. However, owing to the very short half-lives of $^{82}\text{Rb}^+$ (1.26 min) and ^{13}N (9.97 min), their use was very limited. In the last decade (triggered by the shortage in supply of $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ during 2008–10 period), there was a resurgence in their use, facilitated by the availability of $^{82}\text{Sr}/^{82}\text{Rb}$ generators and hospital cyclotrons that can provide $^{13}\text{NH}_3$.

Although a quantitative assessment of cardiac pumping (left ventricular) function is mostly done using echo-cardiography, it is possible to carry out regional wall motion study and ejection fraction (EF) computation as a part of the myocardial perfusion study. This involves initial imaging with ECG gating, with an injection given to a patient already well-positioned for myocardial perfusion imaging using a radiopharmaceutical. A tracer such as $^{81\text{m}}\text{Kr}$ is used for assessing right ventricular function too, when required.

While perfusion imaging gives information on blood flow, imaging with ^{18}F -FDG or $^{123/124}\text{I}$ -fatty acid analogs provides additional information on the viability of heart muscles, as these mimic glucose metabolism or fatty acid metabolism, respectively.

Fig. 1 Myocardial perfusion SPECT imaging using ^{99m}Tc -sestamibi. A projection view shows the heart on the left side of chest. Short axis views reveal decreased perfusion (yellow arrows) at stress state while normalized at rest.

^{18}F -Flurpiridaz (structural analogue of pyridaben, which is an enzyme inhibitor) is currently emerging as the superior PET tracer for myocardial perfusion (beyond $^{13}\text{NH}_4^+$, $^{82}\text{Rb}^+$), and is in an advanced phase of evaluation. ^{18}F -Flurpiridaz is taken up by binding to a mitochondrial complex 1 (MC1) present in myocardial cells (Liga and Neglia, 2020).

Neurology—brain

The brain is another vital organ, where various functional aspects are of great diagnostic value in determining several disorders. Brain imaging, which was limited to finding out if there is a breach in the blood brain barrier (BBB) due to presence of a tumor, has come a long way with several specific molecules now available to study various functional aspects (EANM Technologist's Guide, 2015).

Brain perfusion imaging can be carried out using radiolabeled molecules that are readily diffused into brain tissue across the BBB. Tc-99 m HMPAO and Tc-99 m ECD are used for SPECT imaging, and O-15 water is used for PET imaging. These imaging procedures are applied for evaluating ischemic brain diseases or localizing epileptic focus in the brain. Blood flow in the epileptic focus is reduced during the interictal phase and increased during the ictal phase. Since O-15 water has a short half-life of 20 s, repeat imaging is possible with less radiation dose. So, O-15 water PET is often used for visualizing brain function of the volunteers in neuroscience studies.

In-111 DTPA or Tc-99 m DTPA can be used for cisternography. If the radiopharmaceutical is injected into the spinal canal by lumbar puncture, a serial imaging shows the dynamic distribution of the radiopharmaceutical in the cerebrospinal fluid (CSF) space. RI cisternography is effective in evaluating the cause of hydrocephalus or locating the point of CSF leakage.

F-18 FDG PET reflects regional glucose metabolism in the brain. Its practical applications are in the diagnosis of dementia and localizing epileptic focus. Dementia has many different etiologies such as Alzheimer's disease, fronto-temporal dementia, vascular dementia, etc. The pattern of decreased regional glucose metabolism differentiates the cause of dementia. The glucose metabolism of epileptic focus is reduced during the interictal phase.

Multiple types of molecular nuclear imaging are capable of targeting amyloid plaques or tau protein allowing it to be practically applied in degenerative brain imaging (Chandra et al., 2019). Radiopharmaceuticals available for amyloid PET imaging are C-11 PiB, F-18 florbetaben, F-18 florbetapir, F-18 flutemetamol, and F-18 florapronol. Amyloid plaque specific imaging is not only useful for the early diagnosis of Alzheimer's disease, but also for the development of amyloid targeting therapeutics. Accumulation of radiopharmaceuticals from Tau PET imaging is well correlated with the symptom severity of Alzheimer's disease.

Dopamine transporter imaging using radiopharmaceuticals, such as [I-123] N- ω -fluoropropyl-2 β -carbomethoxy-3 β -(4-iodophenyl) nortropane (I-123 FP-CIT SPECT), and F-18 fluorinated-N-3-fluoropropyl-2-b-carboxymethoxy-3-b-(4-iodophenyl) nortropane (F-18 FP-CIT) PET, are useful in the diagnosis of Parkinson's disease (Brooks, 2016). It differentiates Parkinson's disease from other causes of Parkinson's syndrome, such as essential tremor, progressive supranuclear palsy, dementia with Lewy bodies, etc.

F-18 FDG PET is not practical for the diagnosis of brain tumor, except for glioblastoma or CNS lymphoma, since the normal glucose metabolism of the brain is high. Instead, O-(2- ^{18}F -fluoroethyl)-L-tyrosine (^{18}F -FET) or (S- ^{11}C -methyl)-L-methionine (^{11}C -MET) is used since they are taken up by the tumor through L-amino acid transporters and, in normal brain, the background is low. These imaging procedures are used for the initial diagnosis, recurrent detection, and treatment monitoring of the various neurological disorders.

Oncology—cancers

F-18 FDG PET is the most popular imaging choice for oncology (Nabi and Zubeldia, 2002). It reflects glucose metabolism and malignant tumors that consume glucose through aerobic glycolysis, which is known for the Warburg phenomenon. Since molecular imaging does not show anatomical structure in detail, in recent years most F-18 FDG imaging procedures are done in a combined system of PET and CT (PET/CT). FDG highlights the tumors on the anatomical imaging from CT scans (Fig. 2). Since oncologic PET/CT imaging covers the torso or the whole body, it is useful for staging work-up by detecting distant metastasis. F-18 FDG PET/CT is also applicable in detecting recurrence and in treatment response monitoring of cancers. Presently, a new hybrid system combining PET and MRI (PET/MRI) is commercially available. It has an advantage of reducing the radiation dose from CT and better delineation of anatomical structure in the soft tissue and the brain (Singnurkar et al., 2017).

As new molecular targets are discovered, new molecular specific cancer imaging systems have been developed. Somatostatin receptor imaging was developed for neuroendocrine tumors (NET). NET cells are highly expressed somatostatin receptors on the surface. In the last decade, In-111 octreotide scan has been used for the diagnosis of NET. Recently, somatostatin receptor PET imaging using Ga-68 DOTATOC (DOTA-Tyr³-octreotide), DOTATATE (DOTA-Tyr³-octreotate), and DOTANOC (DOTA-Nal³-octreotide) were introduced. While well differentiated NET shows high uptake of these radiopharmaceuticals, poorly differentiated NET favors the uptake of F-18 FDG, rather than the former. These somatostatin receptor imaging techniques are useful for selecting appropriate patients for peptide receptor radionuclide therapy (PRRT) with the same target (Fani et al., 2012).

Prostate cancer is generally not well visualized by F-18 FDG PET. Prostate cancer expresses prostate specific membrane antigen (PSMA) on the surface of the tumor cell. Recently, PSMA specific PET imaging is under clinical trials (i.e., Ga-68 Glu-urea-Lys(Ahx)-HBED-CC (PSMA-11), Ga-68 Glu-CO-Lys[(Sub)DLys-DPhe-DTyr(3I)-DOTAGA] trifluoroacetate (PSMA I&T), Ga-68 DOTA-GUL (Glu-urea-Lys), F-18 PSMA-1007, etc.). These imaging techniques have roles for staging, detecting recurrence, response monitoring of treatment, and selecting patients for PSMA targeting PRRT (Ahmadzadehfar et al., 2019).

Whole body bone scan has been used for detecting bone metastasis. Radiolabeled bisphosphonates such as Tc-99 m methylene diphosphonate (MDP), Tc-99 m hydroxy methylene diphosphonate (HDP), and Tc-99 m 2,3-dicarboxy propane diphosphonate (DPD), etc. are administered and images are obtained by a gamma camera or a SPECT/CT system. The incidence of bone metastasis from breast cancer, prostate cancer, and lung cancer is high. Thus, even if there are no signs or symptoms suspecting bone metastasis, imaging is indicated in order to detect hidden bone metastasis. Bone scan is not only helpful for malignant lesions but also for benign bone and joint lesion since the radiopharmaceuticals accumulate in inflammatory tissues. Such bone scans are also capable of detecting osteomyelitis, and various arthritis, such as degenerative, rheumatoid, and septic arthritis. F-18 bone PET shows whole body bones and joints and is also useful for malignant and benign bone and joint lesions.

Tc-99 m nano-colloid is used for detecting sentinel lymph node (SLN) during the operation of cancers. SNL is a first draining lymph node from the primary tumor. Some tumors, such as breast cancer and melanoma, spread mainly through lymphatic vessels.

Fig. 2 Whole body F-18 FDG PET/CT scan shows lung cancer in the left hilar area (arrow). (A) is a whole body frontal view. (B and D) are transverse section images crossing lung mass in the chest from CT and PET, respectively. (C) is a fusion image of (B and D). The normal brain is bright since it is the most glucose consuming organ. There are no other abnormal hypermetabolic lesions in the scanned body.

If patients are in the early stage of cancer, minimal surgery is recommended. However, minimal surgery is only warranted when the primary tumor is proven not to spread via lymphatics. After Tc-99 m nano-colloid is subcutaneously injected near the tumor, it propagates via lymphatics. A surgeon can detect a SLN using a gamma probe during an operation (IAEA, 2015; Moncayo et al., 2019). After picking out the SLN, a pathologist may look at it under microscopy and decide the involvement of tumor. If SLN is free from metastasis, only minimal surgery is warranted.

Other organs

Various radiopharmaceuticals for organ specific physiologic imaging are also available. Thyroid tissue has sodium iodide symporters (NIS). NIS pumps in iodide, as well as technetium, to the thyroid cells. A thyroid scan using I-123, I-131, or Tc-99 m reveals the function of thyroid glands. It differentiates Grave's disease, and subacute thyroiditis, from patients with hyperthyroidism (Fig. 3).

Tc-99 m N-(2,6-dimethyl-phenyl-carbamoyl-methyl)-iminodiacetic acid (HIDA), Tc-99 m diisopropyl iminodiacetic acid (DISIDA), or Tc-99 m mebrofenin is used for hepatobiliary scans since they are taken up by hepatic cells and excreted through the biliary tract. It shows hepatobiliary function and can diagnose cholecystitis (inflammation of the gall bladder) in patients with right upper quadrant abdominal pain.

Pulmonary embolism (PE) is a blockage of an artery in the lungs by a substance that has moved from elsewhere in the body through the bloodstream. It requires emergency attention when patients have sudden dyspnea (shortness of breath) and/or tachypnea (rapid breathing). Deep vein thrombosis is the most common cause of PE. If the patient is not treated with heparin as soon as possible, the mortality rate is high. Mismatch findings in lung perfusion and ventilation scan is practical in the diagnosis of PE. PE shows the defect of pulmonary artery blood flow while ventilation is normal. Tc-99 m macro-aggregated albumin (MAA) is used for lung perfusion scans and Xe-133, Tc-99 m DTPA aerosol, or Tc-99 m Technegas are used for lung ventilation scans.

Some radiopharmaceuticals are readily excreted through the kidney and the urinary system. Renal functioning can be evaluated using Tc-99 m DTPA or Tc-99 m mercaptoacetyltriglycine (MAG3). A dynamic scan imaging after injection of these radiopharmaceuticals can then be administered to evaluate renal blood flow, cortical transit, and urinary flow. This is useful for the assessment of renal functions and obstruction of urinary system. Tc-99 m dimercaptosuccinic acid (DMSA) binds to the proximal convoluted tubules in the kidney. It can detect non-functioning cortical tissue in the kidney of acute pyelonephritis (Taylor, 2014).

Therapeutic nuclear medicine

In-vivo therapeutic radiopharmaceuticals are mostly used for the treatment of cancers and thyroid disorders such as hyperthyroidism. Radiation synoviorthesis (treatment of joint disorders where synovium is inflamed) is being practiced in a limited way. Historically, non-systematic treatment of diseases using radiation began soon after radioactive materials were available. Systematic treatment of thyroid cancers and hypothyroidism using ^{131}I and treatment of polycythemia vera (a kind of blood cancer arising from bone marrow) using ^{32}P began long ago. While the use of ^{131}I has been continued for more than 50 years, the use of ^{32}P to treat polycythemia vera is no longer practiced.

In the past 15–20 years, there has been a surge in therapeutic applications using radiopharmaceuticals. This is due to the knowledge about the molecular mechanisms of several cancers, advances in molecular biology, and the availability of highly specific molecules (especially monoclonal antibodies and peptides that bind to the cancer cell surfaces) that home in on the target tissues—most often cancer lesions. Such well-designed targeting molecules, when loaded with a radionuclide, help in specifically delivering the radiation dose to the target lesions. Hence, a huge amount of research has been going on to develop specific therapeutic radiopharmaceuticals to treat various cancers.

Fig. 3 Tc-99 m thyroid scan shows diffuse enlarged thyroid glands (A) in Graves's disease, while faint thyroid uptake (B) appears in the patients with subacute thyroiditis.

Unlike diagnostic radiopharmaceuticals, where a few radionuclides are found most suitable (^{99m}Tc , ^{123}I , ^{18}F , etc.), the ideal radionuclide for in vivo therapy will need to be selected based on the application. Generally high LET radiations such as α and β^- are preferred, but Auger & conversion electrons are also utilized for therapy. While α will be effective within a few cells range, β^- will be able to kill hundreds of cells. Auger and conversion electrons will act within nanometer distances and, hence, these have to be located in the DNA of the cancer cell in order to kill it. The energy of the radiation should match the volume to be treated, and the half-life should match the biological half-life of the product. Apart from these, the production feasibility, logistics, chemical amenability, etc. will also play a role in the selection of the nuclide for therapy. Generally, the radiation dose from a therapeutic radiopharmaceutical is magnitudes higher than that from a diagnostic radiopharmaceutical. Hence, caution is exercised in using therapeutic radiopharmaceuticals to avoid over-exposure of radiation to any non-target organ.

For in vivo therapy, apart from the old well-established ^{131}I and ^{32}P modalities, there are several radionuclides with high potential for therapy. Among these, ^{177}Lu , ^{90}Y , ^{188}Re and ^{153}Sm have evolved and are being used regularly.

Alpha therapy is gaining a lot of attention and several other RNs (Table 2-Chapter 3A, (Venkatesh and Kang, 2021)) have shown great promise and are being explored for clinical use. Some of them are being used in a limited way as investigational drugs. Loco-regional application of radiopharmaceuticals is recently gaining importance for treatment of well delineated tumors such as liver cancer or brain tumor, which can be treated by instilling the radiopharmaceutical within the organ/diseased tissue. In addition, internal radiation using a radiopharmaceutical has been used to treat certain joint disorders, such as rheumatoid arthritis and hemophilia. This treatment, known as "Radiation Synoviorthesis," is also a local application of a radiopharmaceutical. Another way of classifying the therapeutic radionuclides is based on the energy of the particles, which would influence the range of action in tissues (Table 3-Chapter 3A, (Venkatesh and Kang, 2021)).

The most common situations where therapeutic radiopharmaceuticals have been used successfully are briefly described below.

Radioiodine I-131 has been used for hyperthyroidism and differentiated thyroid cancer since the 1940s. It destroys both normal thyroid and thyroid cancer cells. This effect reduces the amount of thyroxine made by the thyroid gland and the size of the gland in patients with hyperthyroidism. For the treatment of advanced thyroid cancer, a range of 1.1 ~ 3.7 GBq I-131 is orally administered to ablate remnant thyroid tissues after the patients receive total thyroidectomy. It reduces the probability of thyroid cancer recurrence. If the patients have metastases initially, such as in their lungs, bone, etc., 5.5 GBq or higher dose is given to kill the metastatic tumors (Fig. 4).

Fig. 4 Radioiodine whole body scans after 1st and 2nd 200 mCi (7.4 GBq) I-131 treatments. The first image shows multiple metastasis in the cervical lymph nodes, lung and bones. The second image 6 months after the first treatment shows only normal physiologic uptakes in the salivary glands and bowels. It tells us that the radioiodine treatment is successful to remove all metastatic lesions. Since I-131 emits both gamma rays for imaging and beta rays for treatment at the same time, whole body imaging 3–4 days after treatment is helpful to monitor therapeutic response.

If I-131 binds to other molecules, it follows that molecular behavior in the body. When I-131 is conjugated to meta iodo benzyl guanidine (mIBG), I-131 mIBG, it will channel to norepinephrine secreting cells, not to thyroid cells in the body. It also accumulates in certain neuroendocrine tumors such as pheochromocytoma, paraganglioma, and neuroblastoma. Hence, I-131 mIBG is an effective treatment for an advanced stage for such cancers when curative surgery is not indicated (George et al., 2016).

Bone metastasis is quite common in major cancers of organs such as breast, prostate, and liver. Most bone metastasis shows a high turnover rate of bone metabolism and such skeletal metastatic lesions are extremely painful. Palliation of bone pain using radiopharmaceuticals is an option. Hence, radiopharmaceuticals that are bone seekers are used for bone pain palliation therapy. Analogs of calcium ions, such as ions of Sr-89, Ra-223, or a radiolabeled bisphosphonate [such as Sm-153 ethylene diamine tetramethylene phosphonate (EDTMP) or Lu-177 EDTMP] accumulate at sites of increased osteoblastic activity and reduces cancer mediated bone pain.

Peptide receptor radionuclide therapy (PRRT) is a molecular radiation therapy targeting specific receptors that are expressed on the surface of cancer cells in the body (Fani et al., 2012; Kong and Hicks, 2019). It is one of the important treatment options for patients with somatostatin receptor-2 (SSTR2)-expressing neuroendocrine tumor (NET). Incorporating therapeutic radionuclides such as Lu-177 and Y-90 to the higher affinity octreotide analog (octreotate is associated with prolonged survival) has improved hormone associated symptoms and quality of life in patients with advanced NET. New PRRT is under development to target prostate-specific membrane antigen (PSMA), which is a transmembrane protein overexpressed in prostate cancer. Lu-177 PSMA targeted therapy is under clinical trials assessing its role in patients with metastatic castrate-resistant prostate cancer (mCRPC). PSMA-targeting alpha-particle therapy (TAT) is also in clinical studies. Ac-225 PSMA TAT demonstrates promising antitumor activity even in patients resistant to previous Lu-177 PSMA PRRT (Kratochwil et al., 2020).

Selective internal radiation therapy (SIRT) is a type of internal radiotherapy for liver cancers, sometimes called radioembolization or trans arterial radioembolization (TARE). In this procedure, glass or resin or albumin microspheres containing radioactive Y-90 are infused into the hepatic artery via a catheter, so that they preferably lodge in the vasculature of the tumor. These deliver high doses of ionizing radiation to hypervascular liver cancers such as hepatocellular carcinoma, metastatic colorectal cancer, or metastatic neuroendocrine tumors. The radiation will lead to damage of tumor tissue and control of inoperable liver cancers. Another strategy that is used to treat liver cancers is the localized infusion of radiolabeled (I-131 or Re-188) lipiodol through the hepatic artery (Uccelli et al., 2011).

Radiosynoviorthesis is an effective procedure for treating inflammatory joints, especially in hemophilia and rheumatoid arthritis (Fischer and Mödder, 2002; Chojnowski, et al., 2016). Depending on the size of the joint, various radiopharmaceuticals such as Y-90 (large joints-knee), Re-186 (medium joints-elbow, etc.), or Er-169 (small-finger phalangeal) in a colloidal or particulate form are injected into the joint space. The radiopharmaceutical accumulates in the inflamed synovial membrane by phagocytosis. Local irradiation prevents further destruction of the joint by immunological reactions.

Alpha therapy

Therapy using alpha particles has gained a lot of attention in the past decade. The use of radioactive radium in therapy, soon after its discovery and availability in limited quantities, was empirical and was abandoned owing to the undesired health effects caused due to high radiation levels. With advances in specific targeting, it is now possible to deliver the radiopharmaceuticals accurately in the target lesion, and alpha radiation can be extremely efficient in killing the cancer cells when it is in the lesion, due to their high LET. The alpha emitting radionuclides listed in Table 2 and Table 3 of Chapter 3A (Venkatesh and Kang, 2021) are those pursued currently, while several more have been explored. To date, Ra-223 and Ac-225 have been used in patients with impressive success.

Ra-223 chloride was the first commercial alpha therapy product (Xofigo). It accumulates in metastatic bone lesions and alleviates bone pain and extends survival in patients with prostate cancer [Brito and Etchebehere, 2020]. The initial success of ^{223}Ra chloride led to an exploration of other alpha emitting RNs for therapy, among which ^{225}Ac is currently explored avidly for therapy. ^{213}Bi , which results after four successive alpha emissions from ^{225}Ac , has also been widely studied as a therapeutic radionuclide and is availed from ^{225}Ac in the form of a generator. The longer half-life (10 days) of ^{225}Ac compared to that of ^{213}Bi (46 min) is favorable for bio-distribution within the body.

In recent years, ^{225}Ac -PSMA has shown impressive results in castration resistant prostate cancer patients with metastasis. The success reported by the initial researchers has encouraged and triggered similar work around the world. Those who can access Ac-225 from the stock available, or those who are able to produce some quantities of Ac-225 in advanced cyclotrons, are using ^{225}Ac to carry out clinical trials in treating patients with ^{225}Ac -PSMA. Several groups have reported promising results in scientific journals (Kratochwil et al., 2020; Zacherl et al., 2020; Yadav et al., 2020).

Peptide and antibodies for RN therapy

Targeted radionuclide therapy has grown manifolds in the past two decades, especially owing to the initial success with radiolabeled peptides. Octreotide, the octa peptide analog of Somatostatin, when labeled with In-111 and then with Tc-99 m and Ga-68, gave impressive results in diagnostic imaging of neuro endocrine cancer lesions, which was very useful for planning treatment when the lesions are spread all over the body. This led to the use of the same peptide labeled with a therapeutic RN such as Yttrium-90, and later with Lutetium-177, to treat the lesions, which gave good results. The quest for similar targeting peptides has continued, and in

recent times peptides that specifically bind to Prostate Specific Membrane Antigen (PSMA) that is expressed on prostate cancers have emerged as good candidates.

However, many other peptides (such as vasoactive intestinal peptide), which had also shown great promise, did not yet reach the clinics. Ga-68-PSMA is currently used for diagnosis and suitable patients have been treated with therapeutic RN labeled PSMA such as Cu-67, Lu-177, Y-90, and Ac-225. Among these, Ac-225-PSMA has shown excellent results in the clinical trials and these results have led to concerted efforts to make Ac-225 available for clinical use in adequate quantities (Kratochwil et al., 2020).

Antibodies, natural defense molecules that our body makes, specifically bind to the antigen against which it is directed. These are excellent targeting moiety when the antibody is directed against the tissue/lesion of interest. The invention of hybridoma technology (César Milstein and Georges Köhler invented in 1975; awarded Nobel Prize in 1984) to make antibodies in labs, and especially all of them identical, known as “monoclonal antibodies” (MAb), has been a boon in the treatment of cancers, which express unique antigens on their surfaces. Currently many MABs are used in regular clinics to treat specific cancers (Table 3).

Nearly all of these have also been radiolabeled and studied as a radiopharmaceutical for radioimmunotherapy. However, thus far only two radiolabeled MABs—both against CD20 antigen for treatment of B Cell Lymphoma—have been approved for regular clinical use; namely, Zevalin labeled with Y-90 and Bexxar labeled with I-131.

Theranostics

The concept of “personalized” treatment, based on the distribution of the radiopharmaceutical in the patient’s body, has grown in the past decade. This is especially important when a radiopharmaceutical accumulates to a different extent in the target lesions, in different patients, which is predominantly noticed in patients with neuroendocrine tumors treated with a radiolabeled (Y-90 or Lu-177) somatostatin receptor binding peptide. In these cases, the amount of therapeutic dose given is huge (in the ranges of 3–4 GBq) and the treatment is repeated 3–4 cycles. Dosimetry plays a very important role in therapy. If the exact distribution of the radiopharmaceutical molecule in the patient’s body is accurately determined, it helps immensely to calculate the exact amount of therapeutic radiopharmaceutical dose to be administered. Hence, the same targeting molecule, radiolabeled either with the same nuclide but in different dose levels, or a radionuclide of the same element that is suitable for diagnosis, or a surrogate radionuclide with very similar properties (to ensure the same molecular structure, which will have the same bio-distribution) is used for the diagnostic scan in planning the therapy.

This concept, now known as “Theranostics” was used in thyroid cancer treatment with I-131 iodide (see also (Venkatesh and Kang, 2021)). A small dose of ¹³¹Iodide used to be given for ensuring that the cancer lesions are indeed accumulating the radioiodide and to calculate the therapeutic dose to be administered. This practice is still followed. In the case of thyroid cancers, there are a few kinds that do not accumulate radioiodine, and such patients will need a different treatment.

Some therapeutic radionuclides that emit imageable photons can themselves be used in diagnostic quantities to get the diagnostic scan, as in the case of I-131. But, if there is a choice of another RN with better diagnostic features (no particulate emission, such as SPECT or PET RN), one may prefer to use it to avoid an undesired dose. The choice of I-123 in place of I-131 is such an option. In the case of RNs that are pure beta emitters, such as Sr-89 and Y-90, a suitable surrogate pair is sought for imaging. Although hard beta emitters, such as Y-90, could be followed using Bremsstrahlung radiations, the image quality is poor—leading to inaccurate dose calculations.

Nearly all the current therapeutic RNs have a suitable matched pair RN that can be used to label the same biomolecule and obtain a diagnostic image (see Table 4-Chapter 3A, (Venkatesh and Kang, 2021)).

Table 3 Monoclonal antibodies approved for use in clinics to treat patients.

Mab name	Brand name	Indication for treatment	Year approved
Rituximab	MabThera Rituxan	Non-Hodgkin’s lymphoma (NHL)	1997
Trastuzumab	Herceptin	Breast cancer	1998
Alemtuzumab	Campath Lemtrada	Chronic myeloid leukemia	2001
Cetuximab	Erbix	Colorectal cancer	2004
Bevacizumab	Avastin	Colorectal cancer	2004
Panitumumab	Vectibix	Colorectal cancer	2006
Ipilimumab	Yervoy	Metastatic melanoma	2011
Pertuzumab	Perjeta	Breast cancer	2012
Ramucirumab	Cyramza	Gastric cancer	2014
Nivolumab	Opdivo	Melanoma, NSCLC	2014
Pembrolizumab	Keytruda	Melanoma	2014

Conclusion

The applications of radiopharmaceuticals in nuclear medicine are vast, growing and constantly evolving to offer new products and new strategies to help the physicians from multiple specialties in the management of patients and monitoring the treatment. The United Nations Scientific Committee on the Effects of Atomic Radiation 2008 Report (UNSCEAR, 2008) estimated that 32.7 million global diagnostic nuclear medicine examinations are performed annually. The role of nuclear medicine is unique and often the nuclear medicine studies provide unequivocal contributions towards patient care.

Glossary

ADME The absorption, distribution, metabolism, and excretion—here used in the context of a drug and its behavior in the body.

Assay A method to measure a specific chemical/biochemical/hormone.

Inhibition In the biological assays and nuclear medicine, inhibition refers to the prevention of binding of the radioactive molecule with the receptor or to the tissue of interest.

Lead molecule A chemical entity that has the potential to be developed as a drug.

MAB Monoclonal antibody—antibodies that are derived from the same “clone” or a single antibody producing cell that has been multiplied, having identical characteristics and behavior.

MARG Microautoradiography—micro auto radio graphy—a technique wherein a frozen finely sliced (thickness in microns) section of a tissue is imaged to get the information on the distribution of the radionuclide present in it. This technique can provide information at cellular level and used to understand the migration and distribution of the radiolabeled molecule in animal/plant studies.

PET Positron emission tomography—An imaging technique in nuclear medicine wherein a positron emitter is used as the radiolabel.

QWBA Quantitative whole-body autoradiography—a technique in which the distribution of radioactivity (radiolabeled molecule) in the whole body (various tissues and organs) is imaged and quantitatively determined. Generally, QWBA studies are carried out on animal models (rats or mice, etc.) and the data obtained is very useful in the ADME studies in humans. QWBA studies are common in new drug development, to assess the drug distribution in various tissues and organs, which forms a part of comprehensive ADME studies.

Radioisotope Unstable isotope of an element that emits radiation.

Radiolabeling Attaching a radionuclide to a molecule. Generally radiolabeling is achieved through synthetic chemical methods.

Radiopharmaceutical A drug formulation containing radioactivity, used in nuclear medicine for diagnostic imaging or therapy.

Radioreceptor assay An assay that uses radiolabeled molecules that bind to specific receptors.

Receptor Molecular structures within or on the surfaces of cells in biological systems to which specific molecules bind and cause biological responses. For example, in the brain, the dopamine molecules bind to specific proteins on nerve cells in the central nervous system and induce neuro transmission actions.

RIA Radioimmuno assay—a competitive binding assay wherein a radiolabeled ligand is used as the tracer and a specific antibody of the ligand is used as the binding molecule (see [Venkatesh, 2020](#) for more details).

RN Radionuclide; an isotope of an element that is unstable and emits radiation (such as alpha, beta or gamma rays) to transmute into a different nuclide which is more stable.

SPA Scintillation proximity (radioligand binding) assays.

*Retired.

SPECT Single photon emission computed tomography—An imaging technique in nuclear medicine wherein a gamma ray emitter is used as the radiolabel.

Target organ/tissue The organ or tissue that is the focus of study.

Introduction

Drug development is a field of great interest. The efforts to combat diseases with better efficiency is a never-ending exercise owing both to the onslaught of new diseases as well as better understanding of the disease process. All of this inspires the strategy to combat the disease in the best possible way. Drug discovery and development is a multi-step process, and generally it is at least a decade (most of the times much longer) from the time of conception to the time a drug reaches the clinics. The various steps in new drug development and proving its clinical utility through multi-stage clinical trials are not only time consuming, but also very expensive, often leading to potential promising molecules (the key components of importance in a new drug) being abandoned half-way.

The various steps in a new drug development are

- Concept/design of a lead molecule, based on the understanding of the biochemistry of the disease/organs/mechanism;
- Synthesis and testing of a set of lead molecules (often could be hundreds of molecules with similar traits, but a few to be chosen based on actual efficacy);
- Studies on the biological half-life in the body—to ensure desirable retention period and adequate clearance from the body with minimal unwanted effects and maximal efficacy in treatment;
- Testing the hypothesis of drug efficiency—through pharmacological effects and biological distribution and metabolism of the drug inside the body, including localization and retention in target organ/tissue;
- Testing the absence of undesirable side effects—through none or minimal localization in non-target organs; and
- Clinical trials in multiple stages to prove the efficacy in actual clinical settings. This often starts with a small group of volunteers/patients and subsequently expanded to prove the usefulness of the drug beyond doubt in a larger disease population (**Fig. 1**).

The progress of a drug from laboratory to preclinical and clinical stages is an intensive process and it is essential to collect statistically valid data for analysis and interpret the results at each step for planning further experiments. New drug development is a multidisciplinary activity and pharmaceutical industries adopt suitable scientific and technical developments in related fields to increase the efficiency, reduce the cost, and to increase the percentage of the success rate. Taking advantage of the fact that radiotracers can be detected and measured in extremely low amounts (high sensitivity) and can be precisely located, quantified, and imaged, they have been used in new drug development over many decades (Lindner and Link, 2018).

Strategies in the use of radiolabeled molecules

Radiolabeled molecules can be used in each of stage of drug development (Uhl et al., 2015), albeit with different strategies/principles. The lead molecules, when labeled with a genuine radiolabel, would be chemically identical to the unlabeled counterparts in their biological action and, hence, can provide valuable information on the biological activities, physiological clearances, target/nontarget accumulation, etc. An example would be replacing the stable carbon atom, C-12, in the molecule with the radioactive C-14 or C-11 atom. In technical terms, these radioactive labeled compounds are used in nonclinical studies to assess drug absorption, distribution, metabolism, and excretion (ADME) (Marathe et al., 2004).

For example, Serotonin is an important neurotransmitter and optimum serotonin levels are essential for mental wellbeing. Molecules that can bind to a specific serotonin receptor (subtype 2C) in the brain hold promise for use as drugs to treat several disorders of the human central nervous system. These molecules were radiolabeled with carbon-11, and positron emission tomography (PET) imaging studies were carried out to study the kinetics of the proposed drug molecules in the body (Neelamegam et al., 2014).

Such information helps in the selection of promising molecules for taking to the next step. At an advanced stage of development, genuinely labeled drug molecules provide unequivocal proof of the drug action and localization in the desired target regions. This

Fig. 1 Radiolabeled molecules and radiopharmaceuticals in drug development.

strategy is being increasingly used in drug discovery/development to understand the biological behavior of the molecule. This strategy is predominantly research oriented and calls for dedicated radiolabeling and testing facilities.

Another approach is the use of an established diagnostic radiopharmaceutical that is used to get information on the status of health of an organ or a system. If the efficacy of a new drug to treat the diseased condition is to be tested, diagnostic scans using the established radiopharmaceuticals before and after treatment can provide invaluable information. For example, ^{18}F -Fluoro deoxy glucose (^{18}F -FDG), is an analog of glucose, which is extensively used in oncology to image cancerous lesions in nearly all types of cancers. A promising new drug for treatment of a cancer can be tested for its efficacy by imaging the patient using ^{18}F -FDG at various time periods after administering the drug under trial. In this case, the radiolabeled molecule used is a well-established commercially available radiopharmaceutical, but the studies are research oriented. In this second approach, an established radiopharmaceutical that may be obtained commercially is used for checking the action/efficacy of the drug candidate either in preclinical or early phases of clinical trial.

In both approaches, these strategies help in screening a large number of molecules, ascertain biological in-vivo behavior (especially distribution and excretion pattern), and in certain cases, check the efficacy of a new drug. All these together reduce the time for new drug development.

Radiotracer-based assays

Yet another use of radiolabeled molecules in drug research is the use of radiotracer-based assays (Enna, 1984) such as radioligand receptor assays (or radioreceptor assays) and radio immuno assays (RIAs). While the use of RIAs is limited, radioreceptor assays have long been used as a part of new drug discovery process. With the advances in understanding the actions of hormones and drugs, for most drugs and hormones there exists a receptor site on membranes to which the substance must attach in order to evoke a biological response. This has been extremely useful in drug research to test if the molecule under study binds to the specific receptor, which is the first step for obtaining the desired drug effect.

Radioreceptor assays, based on the principle of competitive protein-binding methods, (similar to the radioimmunoassay described briefly in Venkatesh (2020)) were developed in this context. Radioreceptor assays are highly sensitive, reliable, and are simple and rapid to perform (Houghten, 1993). In a nutshell, in radioreceptor assay, a small fixed amount of the receptor protein on the membrane/cell to which the drug is designed/desired to bind is reacted with a fixed amount of the radiolabeled ligand that specifically binds to this receptor. Iodine-125 is the most commonly used radioisotope in radioreceptor assays and tritium (H-3) has also been used in some cases. At the end of the reaction, the receptor bound ligand and free ligands are separated using a suitable technique. If the reaction mixture contains another molecule that can bind to the same receptor, this would compete with the radio-labeled ligand to bind to the receptor. As the receptors are fixed and limited in number, such a competition would lead to decrease in the amount of bound radioligand and this decrease would be proportional to the amount of the competing molecule. When the molecule to be tested for its drug action is added in such a competitive reaction, the affinity of the molecule can be gauged from the extent of decrease in radioligand's binding. A receptor protein and a radioligand with high affinity for this receptor are the main ingredients for radioreceptor assays and the key to developing a successful receptor ligand assay is identifying the appropriate reagents, the reaction parameters, and the separation methods.

Radioligand receptor reactions are usually equilibrium studies, and the two commonly used designs for these assays are saturation assays and competition assays. These assays are sensitive (due to the high sensitivity with which the radioactive labels can be measured) and highly specific (due to the highly specific nature of receptor-ligand interaction). Different types of receptor preparations, such as proteins isolated from cell fractions or the whole cell or even tissue sections, could be used in these assays. With advanced developments in cellular and molecular biology, it has become possible to synthesize the receptor protein in the desired quality, which reduces the variations and increases the accuracy of the assay results.

Scintillation proximity radioligand binding assays (SPA) is a variant of radioligand receptor assay that does not need the separation of receptor bound and free fractions of radioligand. In SPA, the radioligand is labeled with a low energy beta emitter such as carbon-14 or tritium (H-3) or Auger electron emitter such as iodine-125 and the receptor is immobilized on a solid matrix which also encompasses a scintillant, that emits a light signal when it is excited by a beta particle or an Auger electron. In SPA, the light signal is emitted only when the radioligand is bound to the receptor and this is known as homogenous format, which allows monitoring association and dissociation of the radioligand without disturbing the reaction equilibrium. The progresses in biological and chemical sciences have resulted in conceptualization of a large number of target molecules and possibilities of synthesizing limitless drugs candidates to choose from. This has revolutionized drug screening methodology and achieved high throughput. SPA based radioreceptor assays, along with automation in radioactive counting systems, are being used widely in drug research (Cook, 1992, 1996) for determining drug affinity, drug interactions, receptor subtypes, and receptor concentrations. Radioreceptor assays have been applied to quantitative determination of hormones, neurotransmitters, and drugs. The radioreceptor assay of benzodiazepines is a typical example.

Radiolabeling of molecules and molecular imaging

In the early days, drug molecules were commonly labeled with long lived radioisotopes such as H-3 or C-14, which are pure beta emitters that emit low level beta radiation, to study drug localization in animal experiments. The radioisotopes were "visualized" by a simple autoradiography, which is a technique that uses X-ray film or phosphor imaging plates or a similar imaging system to study

localization of radiolabeled drug or drug fragments in organ or tissue sections of the animals (Solon, 2015). Autoradiography has been used for decades. With time, this technique has evolved into more sensitive and sophisticated phosphor imaging based quantitative whole-body autoradiography or autoradioluminography (QWBA) and microautoradiography (MARG) techniques, which have much higher resolution. QWBA uses phosphor imaging technology providing high resolution images of the spatial distribution and matching tissue concentrations of drug-related radioactivity throughout the body of laboratory animals. This provides tissue-specific pharmacokinetic (PK) compartmental analysis. MARG is another autoradiographic technique that qualitatively resolves the localization of radiolabeled compounds to the cellular level in a histological preparation. These techniques can provide spatial and temporal distributions in studies with tissue sections and are now used to quantify radioligands at cellular levels, which aids in identification and validation of drug targets.

Molecular imaging is playing an important role in drug development, especially after lead optimization when a drug candidate molecule enters the preclinical study stage. Nuclear medicine imaging, based on molecular interaction of the radiopharmaceuticals, is a truly “functional molecular imaging” and has far better penetration and resolution in comparison with other molecular imaging techniques. The current hybrid imaging systems, such as SPECT-CT or PET-CT, provide anatomical and physiological information, which aids immensely in assessing the localization of the drug molecules studied (Kristensen and Herth, 2017). The current availability of a wide range of radioisotopes and sophisticated, radiolabeling techniques makes it feasible to radiolabel the drug candidates with retention of its biological action and ensure its stability. The radiolabeled drug is generally prepared in very high specific activity and, hence, the actual drug concentration used for imaging studies is extremely low, usually in nano or pico molar concentrations. Hence, it is possible to obtain quantifiable information about the fate of the drug in the body, such as its distribution and retention in different tissues and excretion and metabolism, which helps in the selection of right candidates for further clinical studies.

Radiolabeling the drug molecules with a genuine label calls for labeling the radionuclide (RN) of one of the elements in the composition of the drug. As most of the drugs (biologically active molecules) are made up of elements carbon, nitrogen, oxygen (and occasionally phosphorus, sulfur or iodine), RNs of these elements need to be used in these studies. Further, radiolabeling a drug molecule will need to be carried out synthetically. As the radiolabeled drug is desired to behave exactly in the same manner as its unlabeled counterpart when administered into the body, it is important to retain the structural identity to the maximum extent possible. In the past, molecules have been labeled through “exchange route,” wherein the drug molecule is exposed to a radioactive reactive molecule (especially for labeling with ^3H or radioiodine). But this method has limitations and does not work for all molecules and all radiolabels. Most often, the radionuclide is introduced through a synthetic route, almost like synthesizing the drug.

Unfortunately, there is no RN that is ideally suited for drug related studies for the naturally occurring elements in biomolecules. The isotopes of carbon-11 ($T_{1/2} = 20.4$ min), nitrogen-13 ($T_{1/2} = 10$ min) and oxygen-15 ($T_{1/2} = 2$ min), are very short lived. Phosphorus and sulfur do not have suitable RNs, whereas Iodine isotopes I-123 and I-124 are quite amenable for such studies. However, not all drug molecules will have phosphorus or sulfur or iodine as one of the elements. Hence, C-11, a positron emitter used for PET studies, is the one used most widely in drug metabolism studies. Labeling with C-11 is desirable since the product is chemically identical with the unlabeled drug molecule (Boscutti et al., 2017; Miller et al., 2008). However, it could be challenging if the synthetic scheme is complex and with low yields. The short half-life of C-11 poses practical difficulties for synthesis and limits the studies to short spans. To incorporate C-11 into the drug molecule, a C-11 labeled reactive intermediate (e.g., C-11 methyl iodide, C-11 triflate, C-11 urea, C-11 carbamates, etc.) is used in an appropriate step of the synthetic route of the drug.

Drugs have been labeled with fluorine-18 ($T_{1/2} = 110$ min) as fluorine mimics the hydroxyl group and the radio-fluorinated drugs are studied as analogues. Since F-18 is the most widely used PET radionuclide, it is common to synthesize a series of radio-fluorinated compounds based on the pharmacophore of the drug, and evaluate them, in order to develop a potential diagnostic radiopharmaceutical.

Such radiolabeling demands good synthetic skills and a good synthetic laboratory with remote handling facilities. Besides the low yields, there are several additional challenges to ascertain their identity with the candidate molecule. These radiolabeled drugs are also required to fulfill the criteria of purity (often in the 95–98% range) and safety before they can be used in animals and humans for any studies.

New drug development and use of radiotracers

A large number of drugs have been studied for their efficacy using molecules labeled with F-18 and other PET radionuclides (Donnelly David, 2017; Matthews et al., 2012; Miyoshi et al., 2011).

As mentioned earlier, the drug molecule may be radiolabeled and administered in the body to study its behavior, or a well-studied radiopharmaceutical may be used to monitor the efficacy of treatment. For example, the drug Docetaxel was labeled with carbon-11 to study its localization and clinical action through PET imaging (van der Veldt et al., 2013).

There are several radiotracers molecules that are very well characterized for their binding affinity with certain targets. Such radiotracers, when produced as per regulatory requirements of safety and quality, can receive approval from regulatory authorities for use in clinical studies as exploratory new drugs/radiopharmaceuticals. Many such radiotracers are used for clinical trials of new drug development. Development of drugs for central nervous system (CNS) disorders, cancers, and other diseases has immensely benefitted from the use of such radiotracers. Some typical examples are given below.

Dopamine, synthesized by neurons in the brain, plays a vital role in various biochemical pathways. Association of dopamine with neuropsychiatry and movement disorders such as Parkinson's disease is now well recognized. The synthesis, storage, release and metabolism of dopamine is tightly controlled through various enzymatic processes and is also affected by concentration of

specific dopamine receptors. Currently, different radiolabeled molecules specific for these processes are identified. Among these, L-6-[^{18}F]fluoro-3,4-dihydroxyphenylalanine (also referred to as ^{18}F FDOPA) is used to study neuro degeneration of dopaminergic neurons associated with Parkinson's disease. ^{18}F FDOPA is approved by US FDA and is available from commercial producer for clinical use. Two other tracers, namely, ^{18}F Fallypride and ^{11}C Raclopride bind to specific dopamine receptor sub types (D2/D3) and provide information about the receptor concentrations. These established radiotracers are used to study the efficacy of new drugs or new therapies for Parkinson's disease and for comparative evaluation of the receptor binding capacity of potential drug molecules.

Serotonin is another important neurotransmitter and optimum serotonin levels are essential for mental wellbeing. SERT (serotonin transporter) plays vital role in serotonin system functioning. Many of the drugs for treating mental depression and anxiety are designed to act through SERT. The radiolabeled molecule ^{11}C -3-amino-4-(2-dimethylaminomethyl-phenylsulfanyl)-benzonitrile (^{11}C -DASB) binds to SERT with high affinity. ^{11}C -DASB is used to obtain information on the functioning of serotonin system in various neuropsychiatry and movement disorders, including the evaluation of new drugs to treat them.

Oncology is among the most benefitted fields by diagnostic nuclear medicine imaging. The use of ^{18}F -FDG, the most used PET tracer, in development of drugs for cancer was mentioned earlier. The emerging knowledge on cancer cell biology has shown that certain types of cancers overexpress specific types of proteins and this has paved way for development of new drugs that target these proteins. Radiotracers that can bind to such specific proteins on the cancer cells have been used for evaluation of these new drugs.

While PET imaging with ^{18}F -FDG is very useful in many cancers, it is not an option for certain cancers such as cancers of brain, prostate, etc. where the ^{18}F -FDG metabolism is high even in non-cancerous cells. In the case of brain, glucose is the main source of energy and, hence, ^{18}F -FDG accumulation in a normal brain is very high. Therefore, the uptake in a brain tumor does not show up in the image. This is overcome by the use of another tracer, 3'-deoxy-3'-[^{18}F]fluorothymidine (^{18}F -FLT), which is an analog of nucleotide thymidine and taken up by growing cells. However, ^{18}F -FLT gets trapped in the cell during cell division process, and rapidly growing brain tumors and other tumors accumulate ^{18}F -FLT and enable PET imaging.

Imaging prostate cancer lesions using ^{18}F -FDG is also difficult, as ^{18}F -FDG is normally excreted through renal route, which is close to the prostate gland location. Based on the knowledge that an enzyme known as choline kinase is elevated on prostate cancer cells, ^{11}C Choline and other analogues of choline labeled with ^{18}F (which act as a substrate for choline kinase enzyme) are used for imaging and early detection of prostate cancers. These tracers are also used to test the efficacy of new drugs against the cancers. Along similar lines, prostate specific membrane antigen (PSMA), which is found to be over expressed in prostate cancer cells, has been a successful target for treatment. Various molecules that act as inhibitor of PSMA are being identified, radiolabeled with diagnostic and therapeutic radioisotopes, and are being evaluated in clinical trials.

Table 1 below lists the examples of such radiotracers that have been used in drug research/development for treatment of some of the common diseases. Some of these are established radiopharmaceutical products, which can be obtained from authorized producers for clinical studies.

Radiolabeled antibody therapy

In recent times, there has been a paradigm shift in new drug development. Protein-based biologics, such as monoclonal antibodies (MAB), are increasingly being evaluated for therapy of various diseases. Antibodies have the inherent specificity to bind to the specific molecular targets against which they are produced. MABs that originate from a single source of antibody producing B-lymphocyte cell have well defined and controlled characteristics.

The hybridoma technology, invented in 1975 by Köhler and Milstein (see also [Venkatesh, 2020](#)), enables the creation of immortalized antibody secreting lymphocytes selection of single clones that secrete antibodies with desired binding characteristics that propagate the clones in-vitro. They produce the monoclonal antibodies on large scale, making them far superior to the conventional polyclonal antibodies for application as a drug. Polyclonal antibodies are derived/produced by different B cell lymphocytes and have different binding characters/affinities. This makes it difficult to predict the therapeutic efficiency when used. The hybridoma technology was quickly adopted to produce MABs specific to many target antigens in huge quantities. Currently, other molecular biology-based technologies, such as phage display methods, are also being adopted for large scale production of MABs. With the possibility of production of MABs specific to a large number of target antigens in huge quantities, immunotherapy has evolved as a very promising modality of treatment for several cancers and certain other diseases over the past two decades (see [Venkatesh, 2020](#)). For example, a MAB against head and neck tumors is used as one of the treatment options.

Table 1 Examples of radiotracers used in development of new drugs for some common diseases.

Target receptor/system for drug action	Radiotracer	Disorder/disease
Dopamine D2/3 receptor	^{11}C Raclopride	Neurology, psychiatry
Dopamine transporter	^{18}F Fallypride	Neurology, psychiatry
Serotonin receptors	^{11}C DASB(3-amino-4-(2-dimethylaminomethyl-phenylsulfanyl)-Benzonitrile)	Neurology, psychiatry
Glucose transporter	^{18}F Fluorodeoxyglucose (FDG)	Cancer, cardiology, neurology
Thymidine kinase	^{18}F Fluoro L-Thyroxine (FLT)	Cancer
Choline kinase	$^{11}\text{C}/^{18}\text{F}$ Choline	Prostate cancer
Prostate-specific membrane antigen (PSMA)	$^{18}\text{F}/^{68}\text{Ga}$ -PSMA inhibitors (PSMA11 or PSMA617)	Prostate cancer

In parallel, MABs were explored for use in nuclear medicine for specific targeting—especially cancers and radiolabeled monoclonal antibodies—as radiopharmaceuticals has grown as a specialty field. The increasing use of monoclonal antibodies in treatment of various cancers has often been supported through data obtained on using radiolabeled MABs to prove the targeting action and localization in the tumor tissues. In such cases, where a very large molecule (such as an antibody) is labeled, a foreign label such as radioiodine or Tc-99m has been used since the biological activity is not altered on radiolabeling if it is distant from the active site.

Radiolabeled monoclonal antibodies have in recent years evolved for use as therapeutic radiopharmaceuticals. Several radiometal based radioisotopes (such as Ga-68, Lu-177, Y-90) are being explored for radiolabeling antibodies, both for diagnostic and for therapeutic use (theragnostic), in turn leading to developments for producing these radioisotopes in adequate quantities and quality. The radiochemical strategies for labeling and related preclinical fields have also witnessed growth and various radiolabeled monoclonal antibodies are currently in clinical trials (Vugts Dinielle and van Dongen, 2019; Venkatesh and Kang, 2021). These studies are extremely useful for development of these drugs.

Rituximab, a MAB that binds to an antigen that is specifically expressed by B-cell non-Hodgkin's lymphomas, was the first MAB based drug approved by US FDA. B-cell non-Hodgkin's lymphomas (a type of blood cancer), being inherently radiosensitive, benefited from a radiolabeled rituximab—proving to be clinically significant as it delivered the therapeutic effect of ionizing radiation at the site of cancer tissues. Currently two radiolabeled MABs, Ibritumomab (labeled with Y-90) and Tositumomab (labeled with I-131) are approved as radiopharmaceuticals, both for treatment of B-cell lymphomas. Although the MABs by themselves are used for therapy, the addition of a radionuclide is like a payload that increases the therapeutic effect multifold. Along similar lines, Trastuzumab, which targets specific receptor protein expressed on certain types of breast cancers, is approved as a chemotherapeutic drug. Radiolabeled Trastuzumab is being used for in clinical trials for diagnosis and treatment of these types of breast cancer, with promising results.

Conclusion

The use of established radiopharmaceuticals in drug development is now quite common and often practiced in testing new drugs. With the advances in understanding of diseases at the molecular level, new strategies are evolving in treatment and testing their efficacy through a molecular imaging technique such as nuclear medicine imaging.

In conclusion, the role of radiolabeled molecules is very valuable in providing unequivocal proof of drug action and efficacy and, hence, increasingly used in drug discovery and drug development.

Glossary

3D-conformal radiation therapy (3D-CRT) Three-dimensional conformal radiotherapy is aimed at delivering a conformal dose distribution to tumors through the use of patient specific 3D images in the treatment planning process. Typically CT and/or MRI images are used in 3D-CRT.

Beta particles Beta (β) rays or beta particles are a type of particulate radiation with the mass of an electron emitted by certain radioactive nuclides. There are two kinds of beta rays. β^- rays have a charge of -1 and are identical with electrons. They are also known as negatrons. β^+ rays have a charge of $+1$ and are identical with positrons, which is the anti-matter of electron.

Boron neutron capture therapy (BNCT) A mode of therapy wherein boron-10 containing molecules are administered to localize in the tissues to be treated, after which an external beam of neutrons is focused on the tissue target to cause a B-10 reaction to emit alpha and Li-7 charged particles, which render the therapeutic effect.

Brachytherapy A therapy technique accomplished by placing a source of radiation inside the body, close to the diseased tissues, generally a cancer. (Brachy in Greek means "in contact").

Computerized tomography (CT) A mode of obtaining a three dimensional tomographic image using X rays.

Endovascular radiation therapy (EVRT) or endovascular brachytherapy (EBT) EVRT/EBT is a brachytherapy treatment modality wherein a radioactive source is placed inside the blood vessel for treatment. EVRT/EBT was used to prevent restenosis of coronary arteries of the heart and blood vessels of the extremities after the original stenosis, or blockage, was opened by angioplasty.

External beam radio therapy (EBRT) Use of an external source of radiation for treatment of diseases, generally cancers. Also known as "teletherapy".

Gamma knife A device in which several (typically 200) gamma radiation sources are placed in a spherical geometry for use in stereotactic radiosurgery of cancerous lesions in sensitive organs such as brain.

Gamma rays They have no charge or mass and are emitted from the nucleus of an atom when the atom undergoes transmutation. Emission of gamma rays does not change the atomic number or the mass number of the nuclide. The change is only in the energy levels within the nucleus.

Hadron therapy Use of charged particles such as protons or carbon ions in radiation therapy.

HDR High dose rate of radiation.

IGRT Image guided radiation therapy (IGRT) is a modality in radiation therapy wherein imaging techniques are used during each treatment session.

IMRT Intensity modulated radiotherapy (IMRT) is the mode of radiation therapy in which the intensity of radiation is varied according to the tumor volume so that the tumor tissues receive high doses while the surrounding tissues receive as low a radiation dose as possible.

KV Abbreviation of kilo electron Volt ($\text{keV} = 10^3 \text{ eV} = 10^{-3} \text{ MeV}$) to denote the energy of the X rays/photons derived from an X Ray machine used in radiotherapy.

*Retired.

LINAC Linear accelerator: An electron accelerator used in radiotherapy that can be used in two modes, to obtain either electron beams or photons.

Multi-leaf collimator (MLC) A hardware device having several movable leaf-like structures, usually made of an element with high atomic number such as tungsten, that can be used to shape the beam of radiation from a radiotherapy machine to match the size and shape of the tumor to be irradiated. The MLC is applied to target the beams at only the cancer cells in order to spare surrounding normal tissue. They are particularly useful when treating patients using IMRT (intensity modulated radiation therapy).

PET, positron emission tomography A tracer technology based on using positrons to isolate a tomographic image.

Proton therapy Use of protons of high energy from an accelerator as a focused beam for teletherapy.

Radiation dose The average energy deposited in tissue by ionizing radiation. Also known as the absorbed radiation dose. The SI unit of absorbed dose is Joules per kilogram of tissue (J kg^{-1}) and is known as "Gray" (Gy).

Radiation dosimetry The special field of calculating a radiation dose delivered to the body, including both the target tissues and the other areas when a source of radiation is used in a medical procedure such as radiotherapy or nuclear medicine.

Radiation sterilization The process of sterilization using nuclear radiation. Generally, gamma radiation from cobalt-60 source is used for sterilization.

Radionuclide An isotope of an element, the nucleus of which is unstable and transmutes (transforms; decays) into a more stable nucleus by emission of one or more kinds of radiations (α , β^- , β^+ , γ) or by electron capture. Sealed Radioactive sources: A hermetically sealed radionuclide source

Stereotactic radiosurgery (SRS) and stereotactic body radiotherapy (SBRT) Stereotactic radiotherapy is a non-surgical non-invasive procedure wherein multiple photon beams from different directions are focused to deliver a highly-concentrated dose of radiation to a precise target in a single session. 3D images of high quality and precision are used to program the irradiation machine for precise dose delivery. SRS is the term used for stereotactic radiotherapy of brain and SBRT when other parts of body are treated.

Teletherapy Use of an external source of radiation for treatment of diseases, generally cancers (the term "Tele"-is used to indicate "from a distance").

Introduction

Radioisotopes have been put to numerous applications owing to their unique properties, and medical applications are the most widely known. Radiation and radioisotopes have been used in the healthcare sector from almost the time when artificial radioactive isotopes were available. Over the past eight decades, the scope and varieties of uses of radiation and radioisotopes in healthcare have grown phenomenally and different radioisotopes/types of radiation are used for different applications. Medical applications of radioisotopes can be categorized based on their use, such as for therapy or diagnosis or for obtaining special materials for use in healthcare.

Radiation therapy using ionizing radiation to treat variety of malignant and benign conditions has come a long way since the discovery of X-rays by Wilhelm Conrad Roentgen in 1895 (Connell and Hellman, 2009), the discovery of the phenomenon of radioactivity by Henri Becquerel soon after in 1896 (Sekiya and Yamasaki, 2015), and the existence of radium and polonium in the pitchblende by Curie et al. (1898). Soon after the discovery of X-rays, they were explored for use in treating cancer. Treatment of cancer using radiation is among the most gratifying uses of radiation.

In the early period, low-energy cathode ray tube and radium filled glass tubes placed closed to the tumor, were practiced for giving radiation in a single dose. These initial phases of treatment with X-rays were associated skin toxicities, owing to the poor penetration of X-rays and limitations to treat deep seated tumors. The technological advances prior to 1945 focused on improving the quality and energy of the radiation beams. With the development of megavoltage radiation machines such as telecobalt (^{60}Co ; teletherapy with cobalt-60) and linear accelerators, it was possible to treat deeper seated tumors in the late 1950s. With the understanding of the effects of radiation, dividing radiation dose in multiple fractions was found to improve the tolerance of normal tissues towards radiation. Consequently, since then fractionated radiotherapy has been the common practice.

The approach taken in cancer treatment is either curative or palliative, depending on the extent of the disease and the health status of the patient. It involves one or a combination of the different modalities of surgery, radiation therapy and chemotherapy. The optimal treatment is tailored according to the type and stage of cancer, histopathology of tumor, anatomical location of tumor, and patient factors. In modern practice, generally the treatment is multimodality aimed at balancing the tumor control rate and the toxicities.

Radiation treatment is offered in two different formats: (1) external beam radiation therapy (EBRT) or *Teletherapy* where a sealed radiation source is at placed a distance from the tumor and the radiation is shone upon it, or (2) by placing the source in close contact with the lesion, also known as *Brachytherapy*.

The practice of teletherapy has undergone a sea-change over the past several decades, owing to the innovations/inventions in varied areas such as automation, computation, image processing/modelling, materials, and mechanization as well as advancements

in imaging and cancer biology. Currently, radiation oncology is an ideal non-invasive treatment and achieves maximal tumor control with minimum normal tissue damages.

The field of brachytherapy too has progressed, and sealed radiation sources are used either interstitially within the tumor or kept in the cavity close to the tumor or covering the tumor like a mold. Brachytherapy is continued to be explored as a treatment mode for well localized cancers and a few non-cancerous skin ailments with success in some cases.

Boron neutron capture therapy (BNCT) was conceptualized almost seven decades ago, but it has remained an option followed by very few clinics in few countries. In BNCT, therapy is achieved through alpha particles and lithium-7 ions being produced in situ from B-10 capture of neutrons. While the concept is very attractive, the practical challenges of targeting the cancerous lesion with a large number of B-10 atoms and shining a neutron beam on the lesion have been the major impediments. The research and development in these areas over the past years have yielded impressive results in certain types of cancers and BNCT is currently seen as a promising therapy mode.

Radioisotopes as a source of radiation for sterilization of gadgets/apparatus used in healthcare is termed as “*Radiation Medical Sterilization*” and is employed worldwide widely to sterilize most of the disposables such as syringes, needles, gauze, etc. as well as prosthetics (Kalia, 2021).

Based on similar principles, radiation, although at much lower dose rate, is used to treat the blood to be transfused, to prevent undesirable reactions. “*Blood irradiation*” is mandatory for transfusion in some countries, while in others radiation treated blood is used especially in immune compromised patients.

Another application of radiation is in the production of unique materials for use in healthcare. “*Radiation polymerization*” is well established in industrial applications for production of polymers for use in several areas (Fernando, 2021). In healthcare, radiation polymerized hydrogels are used in the treatment of burns and open wounds. In recent years, radiation polymerized nanoparticles are being explored for use in radiopharmaceuticals, drug delivery systems, and as scaffolds in tissue engineering.

External beam radiotherapy (EBRT) or teletherapy

The majority of radiation treatment is through external beam approach (EBRT or teletherapy), where the radiation is focused on the tumor. Such therapy started with the use of X-rays soon after X-ray tubes were available as a source of radiation, and X-rays of 200–400 KV energy were used in the early times. The availability of cobalt-60 teletherapy machines ushered in the next period of their extensive use followed by the linear accelerators for treatment with photons or electrons. Figs. 1 and 2 show the pictures of a linear accelerator and a patient prepared for radiotherapy treatment with custom made shields being used to protect the healthy regions organs in the face from being subject to irradiation.

The radiation source used in EBRT has further expanded to include a variety of radiation such as protons, carbon ions, neutrons etc. The effect of radiation depends on several factors such as inherent tumor sensitivity, susceptibility of adjacent normal tissue to radiation injury, quality of radiation, etc.

In order to precisely deliver the radiation only to the tumor, which in most cases is not of regular shape, multiple beams of radiation (or a beam of radiation rotated at different angles) are focused on the target from different angles. Further, if the tumor tissue is located in areas such as the chest (which moves while breathing), it is very important not to miss the target area and to ensure precise delivery of radiation. Advances in imaging techniques, computerized treatment planning and reproducible patient positioning systems have enabled to achieve accuracy in delivering the intended treatment. Currently EBRT can deliver the required radiation dose to the tumor volume very precisely.

Fig. 1 Linear accelerator for radiotherapy

Fig. 2 Patient prepared for radiotherapy.

Planning is extremely important in EBRT, to deliver the exact required dose to the tumor volume while protecting the surrounding healthy tissues to the maximum extent possible. Radiation treatment planning is generally performed using dedicated software, which derives input from an image of the tumor to be treated. The software makes precise calculations for passing multiple beams through the target volume (tumor) while protecting the surrounding normal tissues. Computed Tomography images are the most widely used in treatment planning. In addition, if MR (magnetic resonance imaging) scans and PET-CT scans of the patient are available, powerful software is now available to enable fusion of the images for more accurate and precise target delineation and dosimetry.

Several techniques have evolved from the conventional radiotherapy, aiming at maximizing the dose to the tumor with minimal effect on surrounding healthy tissues, while constantly accounting for involuntary body movements. The following are such advanced techniques, all useful and important to treat tumors in sensitive areas such as brain, head and neck, eye, etc.

3D-Conformal radiation therapy

Three-dimensional conformal radiotherapy (3D-CRT) aims to deliver a conformal dose distribution to tumors, while sparing surrounding normal structures. Development of hardware like a multi-leaf collimator (MLC), along with treatment planning software, was revolutionary in advancing radiotherapy—making possible the delivery of 3-Dimensional conformal radiation therapy (3D-CRT). This entails irregularly shaped treatment volumes, reducing radiation dose to the normal surrounding organs by shielding part in irradiated region during radiation dose delivery compared to conventional techniques ([Chopra et al., 2012](#))—Patient specific 3D images, typically, CT and/or MRI images, are used for defining the areas of concern as well as adjacent normal structures. A plan is developed so that the regions of high dose are concentrated within the tumors. 3D-CRT is used to treat tumors that are close to vital organs and structures, such as head and neck tumors, in a way that minimizes exposure of the spinal cord, optic nerve, salivary glands and other important structures.

IMRT and IGRT (intensity modulated radiation therapy and image guided radiation therapy)

Further innovations in inverse-planning software with robust computers enabled the complex computation to be faster and more accurate, leading to the development of intensity modulated radiation therapy (IMRT). With the IMRT, the intensity of radiation beam is modulated to provide tighter approximation of high dose of radiation to the target volume. An iterative algorithm is utilized to reach the specific dose coverage to the target and to minimize the possible dose to the normal tissues. The output defines the shape and distribution of radiation from multiple beam segments. This provides the high degree of conformity to an irregularly shaped target (tumor) and reduces the dose to tissues in close proximity of tumors ([Bortfeld, 2006](#)).

CT based planning provides the ability to precisely target radiation in tumor area; however, variations due to daily set-up and organ motion necessitate the treatment of a larger volume than that of the actual tumors. The technological advancements in the software, as well as hardware, have enabled the medical technicians to overcome the issues of positional errors and physiological motion and allow closer margins for treatment. The current software and hardware packages account for the physiological motions like respiratory motions, changing position of lung tumors, liver tumors, etc. The modern linear accelerators are fitted with an on-board imaging device, which provides diagnostic quality KV X-rays or cone beam CT Radio-opaque “fiducial” markers, which are small dot like structures made of gold, plastic, or another material (placed in the body within or near the tumor to help locate the cancer). They are used at times prior to pre-treatment imaging for better visualization of soft-tissue ([Shirato et al., 2003](#)). When images are obtained prior to treatment, and used to reduce positioning errors, this precision in treatment is known as, image guided radiation therapy (IGRT).

Clinically the IMRT/IGRT have been found to be extremely useful in allowing dose escalation to the tumor and reducing the toxicities. IMRT has become standard in “organ-sparing treatment” for radiation therapy of head and neck cancers. It helps in protecting the salivary glands and reduces radiation related xerostomia, leading to an improvement in the quality of life (Lin et al., 2003; Nutting et al., 2011). IMRT also offers techniques like “dose painting” and “simultaneous integrated boost (SIB)” to individualize dose planning (de Arruda et al., 2006; Konski et al., 2009). However, there are relatively limited randomized trials (Donovan et al., 2007) at present and several studies are on-going. IMRT is routinely used in treatment of cancers of head and neck, prostate and breast.

Volumetric modulated arc therapy (VMAT) is a mode within IMRT, in which the irradiation machine rotates to deliver the radiation dose continuously. This technique accurately shapes the radiation dose to the tumor while minimizing the dose to the organs surrounding the tumor. This mode is very accurate, shortens the treatment time, and uses a lower overall dose of radiation.

TomoTherapy is yet another mode within IMRT, similar to VMAT, in which the radiotherapy couch where the patient lies is moved through a donut-shaped machine. The radiation source in the machine rotates in a spiral pattern around the patient. It is also sometimes called helical tomotherapy.

SRS/SRT, SBRT (stereotactic radiosurgery and stereotactic body radiation therapy)

The “Stereotaxy” implies the use of multiple beams in a precise coordinate system. Although the word “surgery” is used in SRT, it is a non-surgical radiotherapy procedure. This modality of radiotherapy was conceptualized nearly 50 years ago by neurosurgeons and radiation physicists to treat brain tumors (American Association of Neurological Surgeons) and has since then evolved as a sophisticated, 3-D-computerized imaging to precisely focus multiple photon beams from different directions to deliver a highly concentrated dose of radiation to a precise target in a single session. Stereotactic surgery is often the choice to treat brain tumors and head and neck cancers that are difficult to operate. A device known as “Gamma knife” contains about 200 radiation sources placed in a spherical contour (Fig. 3) and is specifically used to treat tumors in brain/intracranial area. An equivalent device using linear accelerator is known as “cyber knife”.

SRS/SRT, when used to treat cancer lesions at other parts of the body, is known as stereotactic body radiation therapy or SBRT. SBRT is recommended for treating tumors involving the central nervous system, lung, head and neck, liver, abdomen, spine, and prostate. SBRT is used in patients who cannot tolerate surgery and when the tumor is difficult to remove.

The phenomenal improvement in precision in radiation treatment has led to a paradigm shift in favor of shorter treatment courses, allowing for the delivery of higher daily radiation dose, thereby reducing the total duration of treatment. This is known as hypofractionated radiotherapy. Hypofractionation treatment has been successfully used in certain cancers such as prostate and breast cancers. Conventional EBRT of Prostate cancers typically takes 8 weeks to deliver 70–78 Gy radiation dose. However, with hypofractionation, within 4–6 weeks it is possible to achieve biologically equivalent effects even though the radiation delivered is less than the conventional mode (Miles and Lee, 2008).

The extreme version of hypofractionation includes stereotactic radiosurgery and stereotactic body radiation therapy. SRS/SRT have been effective in primary and metastatic brain tumors, certain benign conditions such as pituitary tumors, arteriovenous malformations, trigeminal neuralgia, acoustic neuroma, etc., using a single large dose of ablative dose with a highly conformal radiotherapy dose distribution (Leksell, 1951). SBRT is a method used to deliver precise high dose radiation to extracranial site targets within body using either single or small number of fractions, particularly in liver or lung tumors (Potters et al., 2010). The clinical outcomes have been favorable across multiple diseases (Grills et al., 2010; Cox, 2012; Hoyer et al., 2005).

Fig. 3 Gamma knife. The patient's head is placed inside the hollow part wherein a large number of radiation sources are placed in the spherical covering part.

Fig. 4 Bragg peak showing the deposition of energy by charged particles within a short range in tissues.

Hadron (particle) therapy: Hadron therapy is a form of external beam radiotherapy using charged particles rather than X-rays (photons). Protons, carbon ions, or neutrons are generated by a particle accelerator and are delivered to the target volume (Durante and Loeffler, 2010). The charged particles have unique physical and biological properties. They traverse through matter/tissue with little interactions and deposit nearly all their kinetic energy just before the particle comes to rest within a very small volume. This allows a precise definition of the specific region to be irradiated. The peaked shape of the hadron energy deposition is called Bragg peak and has become the symbol of hadron therapy. Fig. 4 shows the Bragg peak.

With the use of hadrons, the tumor can be successfully irradiated with less healthy tissue damage than would be the case using X-rays. In therapy using charged particles, there is a reduction in integral dose, which reduces the risk of complications. There is a growing role of particle therapy in pediatric malignancies—particularly for brain tumors, tumors located near spinal cord, and relatively radioresistant tumors (Schulz-Ertner and Tsujii, 2007). In comparison with 3D-CRT and IMRT, proton therapy has yielded more promising outcomes in local control and survival for prostatic and head and neck and pediatric cancers. Carbon therapy in Japan has shown even more promising results than proton therapy in radioresistant cancers such as melanoma, non-small cell lung cancer and hepatocellular carcinoma (Jiang, 2012). The challenges for particle therapy are the high cost to build the facility, the need for significantly more physical space, and the need for high quality trained staff compared to photon facility centers (Jiang, 2012; Particle Therapy Co-Operative Group, n.d.).

Brachytherapy

In brachytherapy, sealed radioactive sources in the form of wires, needles, seeds or a surface mold/patch are placed directly into or near the cancer tissues to be treated. This procedure is generally limited to well-localized tumors (Skowronek, 2017). Brachytherapy allows a high radiation dose to be delivered locally to the tumor with a sharp decrease of radiation dose outside the tumor. Different types of cancers are treated through different modes of brachytherapy such as interstitial, intracavitary, intraluminal, surface and endovascular. Some brachytherapy treatments are temporary, with the dose delivered over a short time span, and others are permanent placement of the sources within the tissue wherein the dose is delivered over the lifetime of the sources. High dose rate (HDR) mode delivers high radiation dose within a very short time and low dose rate (LDR) mode uses smaller amounts of radiation over longer periods.

Cancers of cervix, prostate, breast and skin are common sites to be treated with brachytherapy. In certain situations, brachytherapy is combined with external radiation therapy. Studies suggest that disease outcomes after brachytherapy are superior to dose escalation with external beam radiation therapy (Jabbari et al., 2010).

In interstitial brachytherapy, the radioactive source in the form of needles or wires is placed within the cancer tissue. This could be temporarily placed for a short time as in the treatment of cancers of breast, head and neck, etc., or could be permanently placed as in the case of prostate cancers (Figs. 5 and 6).

In intracavitary brachytherapy, sealed radioactive sources are placed close to the tumor situated in a cavity, such as the uterus, for a short time. Intraluminal brachytherapy is a mode where the radioactive source is placed within the lumen—such as the trachea, for treatment of oesophageal and bronchial cancers. The surface brachytherapy is applied to cancers that are on the surface such as skin cancers or ocular cancers over which a radioactivity containing mold is placed for specified time to irradiate the cancers.

Endovascular brachytherapy (EBT) is a treatment modality to prevent restenosis of coronary arteries of the heart and blood vessels of the extremities after the original stenosis, or blockage, was treated by angioplasty. It has been proven that radiation decreases the occurrence of restenosis (Rubin et al., 1999). However, with the introduction and wide use of drug coated stents, which are expected to prevent restenosis, EBRT is currently seldom practiced. The following Table 1 lists the salient aspects of different modes of brachytherapy.

Boron neutron capture therapy (BNCT)

BNCT is a therapy modality wherein a boron (Boron-10) containing compound is administered to selectively accumulate in the cancerous tissues followed by irradiation of the tissue with neutrons. The B-10 nuclei capture neutrons and undergo a nuclear

Fig. 5 Interstitial brachytherapy for tongue cancers. Catheters are inserted around the tumor and maintain position with the help of buttons. Catheters are removed after radiation therapy is completed.

Fig. 6 Interstitial brachytherapy for cancer prostate with Iodine-125 seed (permanent implant) covering the entire prostate tumor adequately delivering approximately 150 Gy. Dose to rectum is substantially low.

reaction, emitting alpha particles and lithium nuclei (Fig. 7), both of which deposit the kinetic energy they carry within an extremely short distance, the size of a single cell.

BNCT is attractive for the treatment of well localized, not too deep-seated tumors, as it is possible to deliver huge amounts of energy precisely within the tumor without causing damage to the surrounding healthy tissues. Brain tumors such as glioblastoma and skin cancers have shown promising results with BNCT. The currently used boron compound is an amino acid derivative, *p*-boronophenylalanine (BPA), which has one boron atom per molecule of BPA. Unfortunately, this is not adequate for efficient therapy. Hence, designing a suitable compound with an adequate number of boron (B-10) atoms, delivering it precisely at the tumor site and having a neutron beam that is amenable to use in a clinical setting, constitute the major challenges in the growth of BNCT.

While neutron beams from reactors were used in the past, accelerator derived neutrons are now increasingly used in BNCT to treat patients (Ridikas et al., 2020; IAEA, 2020). Producing neutrons from a charged particle accelerator is cleverly conceived through the reaction of protons (from the accelerator) on a target to result in a nuclear reaction where neutrons are emitted. One such target is beryllium-11 ($^{11}\text{Be}_4 + ^1\text{p}_1 = ^{11}\text{B}_5 + ^1\text{n}_0$) which has been used for availing neutrons for BNCT. These neutrons emitted carry high energy and are generally passed through a slowing-down medium to reduce their energy to epithermal level for use in BNCT.

The potential of BNCT to treat well localized tumors efficiently without causing damage to tissues in the vicinity, is attractive and, hence, active research is underway to make BNCT an option in clinics. A schematic diagram of a BNCT set up for treating patients using accelerator derived neutrons is shown in Fig. 8 (Courtesy Sumimoto Heavy Industries, Ltd., Japan).

Table 1 Radionuclides used in brachytherapy.

Type of brachytherapy	Clinical conditions	Radionuclides used	Comments
Interstitial	Breast cancers	Ir-192; Co-60; Au-198	Useful in specific cases but not common in current times
	Head and neck cancers	In the form of needles, wires	
	Soft-tissue sarcomas	I-125; Pd-103; Cs-131	Small radioactive seeds are permanently placed for therapy of prostate cancers; practiced widely
	Prostate cancers	In the form of small encapsulated seeds	
Intracavitary	Uterine cancers	Ir-192 (HDR) Co-60 (HDR) Cs-137 (LDR) Sealed small pellets used through a device either remotely controlled (HDR) or manually operated (LDR)	Common; HDR is preferred over LDR
Intraluminal	Esophageal and bronchial cancers	Ir-192; Au-198	Most often used following EBRT as boost radiation therapy to increase the efficacy
Mold brachytherapy	Eye/ocular cancers	I-125, Ru-106	Used only in specific suitable cases; not frequent
Intra vascular	Endovascular Radiotherapy (EVRT) for prevention of restenosis	Re-188; P-32; Ho-166; Sm-153; Y-90	Radioactive liquid filled balloons or Ir-192 sources were placed inside the affected (restenosed) blood vessel. Rarely used now

Advances in radiation therapy

The current research in radiotherapy is aimed at the challenges faced in radiotherapy practice.

A typical challenge with clinical radiotherapy is that tumors are frequently located adjacent to the radiosensitive normal tissues. Therefore, the drugs that can preferentially sensitize tumors so that they get destroyed by radiation easily, will be of great interest in oncology. Several radiosensitizer molecules play a critical role by enhancing the anti-tumor effects of radiotherapy. Standard chemotherapeutic agents are commonly utilized to increase the efficacy of radiation therapy.

Radiation causes single and double strand DNA breaks. The double strand breaks (DSB) are generally considered to represent the principal lethal event and desired for radiotherapy. The human body has existing mechanisms to repair DSB and this will decrease the efficacy of treatment. Hence, there has been a growing interest in understanding the mechanism of DSB repair pathways and the ways to block them. Many components of DSB repair pathways have been investigated as therapeutic targets and chemical inhibitors being explored as a possible lead compound for use as drugs to be given in conjunction with radiation (Russell et al., 2003). An example is PARP (Poly ADP-ribose polymerase) inhibitors, which are being studied in several clinical trials with chemotherapy and with radiotherapy (Chalmers et al., 2010; Powell et al., 2010). Similarly an enzyme compound of Histone deacetylase (HDAC) has shown radio-sensitizing properties (Munshi et al., 2005; Zhang et al., 2009).

The other challenge faced is the resistance to radiotherapy in the regions where tumors are hypoxic (low amounts of oxygen). Such hypoxic regions surround “necrosis” (dead cells) that occur due to the uncontrolled growth of cancers. Generally, hypoxic regions are radioresistant. Efforts to develop radiosensitizers that can render hypoxic cells susceptible to radiation are being continued, but clinical success is yet not achieved (Rischin et al., 2010).

There has been extensive preclinical work combining gene therapy and radiotherapy in recent past. Replication-defective viruses have been used to deliver radio sensitizing molecules (such as prodrug, cytokines, tumor suppressor genes and immune activating compounds), which have shown promising results (Harrington et al., 2010).

Applications of radiation processing

Apart from the therapy applications discussed above, radiation processing plays a unique role in healthcare, as briefed below.

Radiation sterilization: Sterilization of medical products such as syringes, sutures, needles, prosthetic implants, etc. through irradiation using gamma rays from Cobalt-60 is the most common practice for large scale medical sterilization (Kalia, 2021). Currently, over 200 gamma irradiators all over the world sterilize 12 Million cubic meters of single use medical devices annually. Radiation sterilization is an attractive option as it does not use or emit pollutants (hence, is environment friendly) and affords the possibility of large-scale operations.

Blood and tissue irradiation: Blood and tissues are irradiated with gamma radiation, most often using Cesium-137, to prevent the proliferation of viable T lymphocytes and render them safe for transfusion/grafting into patients, and to prevent the “Transfusion associated Graft-Versus Host Disease (TA-GVHD)”. TA-GVHD, though a rare complication, has a fatality rate greater than 90% and immune compromised patients are more susceptible.

Radiation processed materials in healthcare: The use of novel materials obtained through radiation processing is an actively growing area. The possibility to produce polymeric material of required physical characteristics, size and in a reproducible manner have led to the exploration of such novel materials in different applications in healthcare. Among the established products, “Hydrogel” is a polymeric material that is breathable and capable of absorbing large quantities of liquids. It is widely used to treat the skin conditions such as burns, bed sores, etc. Radiation processing is an established way to produce sterile hydrogels (Fernando, 2021). The use of polymeric scaffolding materials for tissue growth and the use of nano polymers as substrates for use in radiopharmaceuticals are some of the areas of application being actively pursued currently.

Conclusion

External beam radiation therapy for treatment has a huge impact on the management of cancer patients and the advances in radiation teletherapy over the past few decades have resulted in a phenomenal improvement in success rates. Currently EBRT is a component of therapy strategy in a huge fraction of cancer patients. The understanding of newer avenues such as biological, molecular, immunological and genetic intervention, all of which hold promise are being explored to enhance the efficacy. Brachytherapy has a unique role in treatment of malignant cancers and non-malignant situations. The potential of brachytherapy for treating uncommon rare cancers is explored resulting in new developments in this area, albeit of limited usage.

BNCT has shown promising results in the recent years and this could lead its use in clinics in more countries in near future.

Introduction

Crop production is central to food security, especially as global population is predicted to surpass the 9 billion mark by 2050. Adverse conditions for crop production resulting from a changing climate, such as increasing temperatures, frequent droughts, soil salinization, changing intensities and frequencies of disease and pest incidence and their transboundary spread, are all factors that further threaten food security. Genetic diversity of crop species achieved through breeding, and optimal soil and water conditions in the growing environment through management, constitute the essential requirements for increasing crop production.

Breeding improvements in crops include increasing crop yields, improving quality, and enhancing resilience to adverse conditions such as diseases, pests, and environmental stress including drought, heat, salinity etc. Management and agronomic practices address soil, water and nutrient requirements of the crop to ensure increased and sustained production. This chapter discusses nuclear, isotopic and related techniques used in creating new genetic diversity for crop improvement, and in the management of soil, water and nutrients for crop production.

Mutation breeding for crop improvement

Improvements in the productivity of plant species that are currently grown as food, feed or cash crops have been the result of domestication, diversification and breeding over centuries. Of particular note in the most recent past is the spectacular increase in productivity of rice and wheat from systematic plant breeding combined with increased fertilizers during the Green Revolution of the 20th century.

Mutations, or naturally occurring genetic variation, followed by genetic recombination, constitute the bases for crop improvement as it did for the domestication of crop plants more than 12,000 years ago. Currently about 2500 species have undergone selection by humans and domestication at one level or other, and 250 species are considered fully domesticated (Meyer and Purugganan, 2013). During the process of domestication, plant phenotypes (characteristics) or traits that were amenable to cultivation were selected by humans in a unique form of directed evolution. The selected plant phenotypes in the early stages of domestication included inflorescence architecture, non-shattering of seeds, loss of seed dormancy, size and number of seeds, determinate growth habit, and others. Subsequently, diversification traits were selected, and most recently crop improvement has been achieved through systematic plant breeding.

However, it was only as recent as the last few decades that the mutations or genetic variations underlying the selected phenotypes in domestication, diversification and breeding were identified, with the advent of molecular genetics and more recently, genomics technologies. One example is the evolution of present-day maize from its wild progenitor, teosinte, as a result of spontaneous mutation in the genetic locus, *teosinte branched 1 (tb1)*, encoding a transcription factor that controls shoot architecture or the branching pattern of the plant (Doebley et al., 1997). The dwarf phenotypes of rice and wheat that drove the Green Revolution during the 20th century were identified to be the results of mutations in the genes, *Reduced height (Rht)* in wheat, and *semidwarf1 (sd1)* in rice, involved in the regulation of the biosynthesis (synthesis of a molecule or compound in a biological system), or of the biosynthesis itself, of the plant growth hormone, gibberellin (Hedden, 2003).

Mutations are the ultimate source of all genetic diversity, and genetic diversity in turn is centric to crop improvement. Mutations in the DNA can occur spontaneously in nature or can be induced, and this together with genetic recombination leads to the development of new crop varieties. Since the last century, plant breeders have been systematically utilizing the existent natural diversity in germplasm pools (genetically divergent groups of plants) of crop species to select improved varieties. The extent of genetic gain or improvement achieved through plant breeding is dependent on the extent of genetic diversity in the base germplasm pool. In the major crops of the world such as maize and rice, the historic intensive breeding of locally adapted germplasm has led to a significant reduction of genetic diversity. Low genetic diversity is also encountered in vegetative propagated crops.

Induced mutations facilitate the creation of new genetic diversity in the germplasm allowing the development of new and improved varieties, while also enabling the acceleration of crop improvement. This accelerated genetic gain is critical to meet the food security needs of a growing global population. It is also crucial to facilitate crop adaptation to increasing temperatures, frequently occurring droughts, rapid salinization of soils, transboundary pests and diseases, and other adversities that accompany a changing global climate.

Nuclear techniques in mutation breeding—A brief history

Spontaneous mutations have been the bases of domestication for thousands of years. The term “mutation” and the practice of mutation breeding, however, evolved only as recently as the 20th century. Hugo de Vries, one of the rediscoverers of Mendel’s laws of inheritance, along with C. Correns and E. von Tschermak-Seysenegg, was researching on the evening primrose *Oenothera lamarckiana* during the late 19th century, when he discovered heritable variation that did not follow a Mendelian inheritance pattern. He coined the term “mutation” in 1901 to define the mechanism that creates heritable change in an organism. In the introduction to his publication, *Die Mutationstheorie* (Volume I), in 1901, De Vries speculated on the possibility of artificially inducing mutations in species. In 1904, he had already indicated the possibility of artificial mutation induction using the new types of radiation discovered in 1895 and 1900, respectively, X-rays and γ -(gamma)-rays. The work of De Vries can be considered as the starting point of the science of mutation breeding for crop improvement.

Irradiation of plant material for inducing mutations started soon after the discovery of X-rays. However, the first definitive proof for the induction of mutations within genes came from H. J. Muller in 1927 who showed that treating sperm in the male fruit fly, *Drosophila melanogaster*, with high doses of X-rays resulted in very high mutation rates of sex-linked recessive lethals (a hereditary change), as compared to untreated control parent flies (Muller, 1927). Around the same time, L. J. Stadler, a plant geneticist, was working on inducing mutations in barley, oats, wheat and maize using X-rays and radium rays, and published his first results a year later (Stadler, 1928). Stadler’s studies showed that irradiating germinating seeds produced an eightfold increase in mutation frequencies—relative to irradiating dry seeds, and that the mutation rate was proportional to the dose of irradiation, with the rate for a given dose differing between, and even within species. Stadler, however, was skeptical of the use of induced mutations for crop

improvement. He considered that sufficient variability existed within gene pools of crop plants to allow improvement by conventional breeding, and that newly induced mutations would be linked to other deleterious mutations. Notwithstanding Stadler's skepticism, contemporary plant geneticists including H. Stubbe and coworkers in Germany, and H. Nilsson-Ehle and A. Gustaffson in Sweden, used X-rays and UV-rays to induce mutations in plant species, and the latter became the first to successfully develop genetically superior cultivars in barley through mutation induction (Kharkwal, 2012). A. Gustaffson could probably be called the 'father of mutation breeding'. The first commercial mutant crop cultivar was developed in tobacco through irradiation of inflorescences (floral structures of plants) with X-rays as early as 1934 by D. Tollenaar, and this mutant cultivar, "chlorina," occupied 10% of the tobacco area in Indonesia already by 1936.

Several new mutagens, both physical and chemical, have since been used after the early use of X-rays, radium and UV rays for generating genetic variability. Their mechanism of action at the level of the DNA can vary from single point mutations or base changes to large deletions involving several megabases (large numbers of DNA base pairs). Next-generation genomics technologies have allowed, most recently, the deciphering of the effects of different mutagen sources on the DNA. The use of these various mutagens has given rise to the induction of a wide range of mutations in plant species, several of which have been used in fundamental studies to establish gene-to-phenotype relationships. Mutation studies in the model plant species, *Arabidopsis thaliana*, a small flowering plant with a small and simple-structured genome ($2n = 10$; ~ 120 Mb; few repeats) and the first plant to be fully sequenced, has yielded significant amounts of information over the last 50 years on the molecular biology of plants. These studies also shed light on genes involved in numerous biochemical and hormonal pathways, and morphological and physiological traits. More important, however, has been the use of induced mutations in practical plant breeding for the development of new and improved crop varieties for wide cultivation by farmers.

Mutation breeding took off in the 1950s with several countries, including China, Germany, India, Japan, the Netherlands, Sweden, UK and USA incorporating the technology into major plant breeding programs, resulting in the development of improved varieties of many crop species. Examples of these mutant varieties in food, oil seeds, cash crops, and horticultural crops developed and released for cultivation in the early years of mutation breeding are many. They include the rapeseed variety, Regina II, developed in Sweden and released in Canada in 1953; the induced mutant variety of sweet cherry, Compact Lambert, released in Canada in 1964; the first semi-dwarf rice variety, Reimei, released in Japan in 1966; the first semi-dwarf rice variety, Calrose 76, developed in the USA in the 1970s and integrated into breeding programs in the USA; Australia and Egypt to produce more than 20 new semi-dwarf rice varieties; the mutant grapefruit varieties, Star Ruby and Rio Red, developed in the USA and sold under the trademark Rio Star, which occupies 75% of the cultivated area under the crop in Texas; Todd's Mitcham and Murray Mitcham varieties of *Verticillium*-resistant peppermint released in the USA in 1971 and 1976; and others.

In 1964, the Joint Division of the Food and Agricultural Organization (FAO) and the International Atomic Energy Agency (IAEA) was established at the IAEA headquarters in Vienna to address Nuclear Techniques in Food and Agriculture. At that time, Plant Breeding and Genetics (PBG) was included as one of the five sections within the Joint Division, and this gave impetus to mutation breeding in many Member States. The technical support from the Section has enabled more than 70 developing countries to build capacities in mutation breeding, and improved mutant varieties have been developed and released especially by countries in the Asia Pacific region. The laboratory facilities of the Joint Division at Seibersdorf feature a Cobalt-60 γ -irradiator and an X-ray system, both of which are routinely used for irradiation of seed and vegetative plant material as a service provided by PBG to Member States. The wide establishment of Co-60 irradiation facilities in the 1950s made γ -rays a very popular mutagen source for mutation breeding during this early phase.

By the 1980s, with transgenic research starting to gain prominence, the role of induced mutations in plant breeding started to wane in North America. However, major seed and biotechnology companies in the USA continued to use various forms of mutagenesis to establish gene-to-phenotype relationships, which in turn lead to the identification of candidate genes that could be tested for transgenic trait improvement (Sivasankar et al., 2012). Mutation breeding also remains a popular method for the improvement of ornamentals and vegetables, although information of its use is not publicly available as most of this breeding is by seed companies. In the countries of the Asia Pacific, however, the use of induced mutations in mainstream breeding programs continued in the meantime, and a majority of mutant crop varieties of the world developed to date are recorded for this region. The IAEA maintains the Mutant Variety Database at <http://mvd.iaea.org/>, which is a repository of voluntarily contributed information of released mutant crop varieties. It includes both direct mutants (directly from mutation and selection) and indirect mutants (a mutant parent used in crosses to generate new varieties) (Fig. 1). The database, which is by no means complete, holds 3314 records across 220 plant species at the time of this writing, about 50% of which have originated from γ -ray irradiation. The majority of the records (over 2000) is from the Asia Pacific region, which is followed by Europe. China alone has 810 records in the database, and has been using several mutagen sources including, most recently, ion beam and space irradiation (taking seeds into space for exposure to cosmic radiation).

Mutagens in plant breeding

Mutations can be spontaneously occurring in nature or induced. Induced mutations are derived from specific treatments with physical or chemical mutagens. Mutagenesis with physical mutagens has been the most frequently used method to create genetic diversity for the development of new and improved crop varieties. Physical mutagens include non-ionizing radiation such as ultra-violet (UV) light, and ionizing radiation such as X-rays, gamma-rays, alpha and beta particles, neutrons and ion beams (FAO/IAEA, 2018). Further, cosmic irradiation and laser beam irradiation have also been used to create changes in the plant DNA.

Fig. 1 Current records (voluntary reporting by IAEA Member States) of mutant varieties in the IAEA Mutant Variety Database. (A). Mutant varieties released from the different global regions across the years. Asia is the leading region, and China has the largest number of mutant varieties in the region, followed by Japan and then India. (B). Released mutant varieties across different crop categories. Cereal crops lead, with rice having the largest number of records. The categories of Fruits/Berries, and Flowers/Ornamentals, include tree species and shrubs. "Other" include medicinal species, fodder and forage, grasses, mushrooms etc.

UV light is a non-ionizing radiation with limited tissue penetration that has been frequently used for mutation induction in sensitive plant materials such as pollen grain, single cell-layer tissues, tissue culture material, cell suspension cultures, spores, etc.

Ionizing radiation can remove electrons from molecules in a cell and create free radicals. Free radicals and particle tracks of an ion-beam can break one or both DNA strands, which causes gene or chromosomal changes such as deletions, substitutions, insertions, translocations, duplications, and inversions. When compared with non-ionizing radiation, ionizing radiation penetrates deeper into the tissue and can induce a great number of different types of chemical changes. Hard X-rays with short wavelength are generally preferred rather than soft X-rays for mutation induction, due to the higher penetration of the former. Specific filters used in hard X-ray production help absorb unwanted soft radiation. The peak operating voltage, thickness and type of filter, distance of tube to target, and dose rate are factors that affect the usefulness of the mutagenesis event.

In the early days of mutagenesis, X-rays were mainly used, but with the advent of gamma irradiation facilities, gamma rays have been used to a great extent. Cobalt-60 (^{60}Co) with a half-life of 5.26 years, and Cesium-137 (^{137}Cs) with a half-life of 30.17 years are the main sources of gamma rays. Gamma rays have been used both for acute and chronic irradiation. Acute irradiation facilities irradiate plants with high doses in a short period of time in gamma rooms or gamma cells. Chronic irradiation facilities installed with gamma radiation sources (^{60}Co or ^{137}Cs) expose plants to low doses of gamma-rays for long periods while growing plants in fields, greenhouses, or environmentally controlled (phytotron) rooms. Such chronic irradiation facilities have been built and operated in several countries such as Japan, Malaysia, Korea and Thailand (Fig. 2).

Alpha and beta particles have been only used to a very limited extent in experimental mutation induction in plant tissues. Thermal (0.4–100 eV) and fast neutrons (200 keV–10 MeV) are also used in mutation induction, although their use has also been limited relative to X-rays and gamma-rays. The most famous example of a crop variety developed from mutation induction by thermal neutrons is Star Ruby, the red-fleshed, seedless variety of grapefruit, developed in 1970. More recently, heavy ion beams and cosmic irradiation are also coming into use in mutation induction for plant breeding.

Many research groups in Japan have created new varieties of various plants and microbes through mutations by heavy ion beams generated by big accelerators. The heavy ion and proton beams belong to high-LET (Linear Energy Transfer) radiation while the radiations of X- and gamma-rays are classified as low-LET. According to recent studies, high-LET radiation has a higher frequency and spectrum of induced mutations due to the ease of inducing single and double strand breaks, not achievable by low-LET radiation. Despite these advantages, high-LET is difficult to attempt in many countries because the construction of an accelerator facility for ion beam irradiation is too expensive, and the number and volume of samples that can be irradiated at one time is limited. Recently, securing gamma-ray sources has become more difficult due to the strengthening of international transportation laws and safety management. Therefore, there are opinions that X-rays and electron beams should be considered again for use in the future instead of gamma-rays. In addition, since the early 1990s, China has been developing several mutant varieties by space-induced mutagenesis using recoverable satellites, spaceships, and high-altitude balloons that carry plant seeds into space.

It should be emphasized that, unlike many people's concerns, radiation used for mutant breeding only uses its transmission energy to change the genes of the living cell nucleus. It does not remain behind or contaminate living things and the environment.

Chemical agents can also cause mutations in cells. These include a special class of alkylating agents such as ethyl methane sulphate, diethyl sulfate, ethylamine, ethyl nitroso urethane, ethyl nitroso urea, and methyl nitroso urea. Chemical mutagens most often affect single nucleotide pairs and generate point mutations. The benefit of using chemical agents is a high mutation rate, simple application, and less damaging effects at the DNA level. However, chemical mutagens have several disadvantages, including difficult penetration in multicellular plant tissues, uneven penetration, low reproducibility, and health-risks associated with poor handling. Beyond physical and chemical mutagenesis, mutations can also be induced by biological means, as with tissue culture techniques, and T-DNA or transposon element insertion (random insertion of the mobile DNA elements in the genome).

Fig. 2 Different gamma radiation facilities for acute and chronic irradiation: Gamma room (above) and Gamma Phytotron (below) of the Advanced Radiation Technology Institute, Korea Atomic Energy Research Institute in Korea.

Mutation breeding has several advantages. First, it is applicable to various plant species and materials such as annuals, perennials, seed or vegetative propagated crops, seeds, stem or root cuttings, tubers, pollen, cell cultures, tissue cultures and individual plants. In other words, radiation-induced mutation breeding can be used to increase the genetic diversity of crops that cannot be improved by conventional breeding through crossing. Second, it can be applied to the breeding of crops lacking genetic resources and can contribute to the expansion of breeding materials. Third, mutants have contributed greatly to the search for new genes in functional genomics approaches. Despite these advantages of mutation breeding, there are limitations in the easy generation of useful variations relative to cross breeding. Optimal dose rate and precise, trait specific selection is critical to capture mutants with useful trait variations, but with minimal effect on the agronomic performance of the plant.

Mutations and functional genomics platforms

The term “functional genomics” implies the determination of gene function at the genome-wide scale. It is essentially the establishment of gene-to-phenotype relationships. A phenotype or trait is a specific observable characteristic of an organism, and for crops it can include yield, stature, disease resistance etc. A trait can be the result of the action of a single gene (simple trait) or a large number of genes (complex trait). Prior to the genomic era, induced mutations were routinely explored in model plant species in order to identify the genes underlying specific phenotypes such as flowering time, morphological changes etc., and to unravel the molecular biology of biochemical and hormonal pathways. Establishment of gene-to-phenotype relations are important both for fundamental studies and for the identification of candidate genes responsible for specific traits. Candidate-gene information can be used to improve desirable crop traits through genome editing or marker-assisted breeding. The seed biotechnology industry uses various types of mutant populations for such candidate-gene discovery, including insertions of transposons or mobile genetic elements, activation tagging, chemical mutagenesis and others. Such candidate-gene discovery has been described from the perspective of developing drought tolerance in maize (Sivasankar et al., 2012).

A mutant population that is systematically developed, maintained, phenotyped and preferably, genotyped as well, can constitute a powerful functional genomics platform. Trait-specific phenotyping for candidate gene discovery in a forward genetics approach (from the phenotype to the gene) and mutant plant recovery through reverse genetics approaches (from the gene to the phenotype)

can both be achieved in such a platform with a single mutant population. An elegant example for such a platform is the Trait Utility System for Corn (TUSC) that was developed and maintained for both gene discovery and product development in the 1990s by the seed company, DuPont Pioneer, now Corteva. The mutations in this case involved transposon insertion. Subsequently, the reverse genetic approach, TILLING (Targeting Induced Local Lesion IN the Genome) has been used to recover mutant plants with point mutations in specific genes from chemically-mutagenized populations. TILLING is a high-throughput, sensitive and cheap approach to identify, from a mutant population, plants with alterations in a specific gene of interest.

A functional genomics platform involving a plant mutant population originating from physical mutagenesis employing X-ray, γ -ray or heavy ion beam applications can also be queried for mutant plants with point mutations or small indels (insertions and deletions) in genes of interest. Instead of the TILLING protocol described above, new high-throughput sequencing of amplicons (amplifications of DNA) of targeted regions in the genome in mutant DNA pools facilitates the recovery of mutant plants harboring mutations in the target genes. Such a functional genomics platform for sorghum, irradiated with γ -ray, has recently been developed at the Joint FAO/IAEA Division, and a bioinformatics package for querying the presence of mutants in genes of interest is in development.

The beginning of the present decade saw the advent of the Genome Editing technology using the CRISPR-Cas9 system and others for site-specific modification or editing of “candidate” genes known to underlie traits of interest. The technology enables a precise (site-specific) change in the genome, in a candidate gene or genetic element. A pre-requisite for genome editing is the identity of the gene that is responsible for a phenotype, the candidate gene. This information is available only from spontaneous or induced perturbation of the genome through mutations, and the subsequent establishment of gene-to-phenotype relationships. Genome editing currently has the advantage of improving simple traits (controlled by one or two genes), when the identity of the candidate gene is known. For all other applications, such as the improvement of complex traits (controlled by several genes) or the improvement of a trait when the identity of the candidate gene is not known, traditional breeding, or even better, mutation breeding, is the best resort.

Speed-breeding techniques for accelerated genetic gain

The time required to develop a new and improved variety in most public breeding programs at present is too long to meet the food needs of a growing population, especially in view of a changing climate that adversely affects crop production. In general, most food crops with a long generation time take about 10 years for the development of an improved variety. Vegetative propagated crops such as ornamentals require only half this time when variability is induced by somatic cell mutation.

Mutation breeding for seed propagated crops is started by subjecting seeds, whole plants, or gametes (pollen, egg cells) to mutagenic treatments. Seeds are the most commonly used initial materials for induced mutation. The seed of a parental line that has been treated to a mutagen is designated M_0 , which upon germination produces M_1 plants. Seed from M_1 plants are grown as M_2 where the first selection can be made for the phenotype or trait of interest. Subsequent advances of generations and selections in each generation is continued for three or four generations to obtain genetically stable mutants. In most countries, selected promising mutant lines are tested in multi-locational field tests under different environments. Promising selections then undergo registration tests of an official agency before registration and release as varieties.

Crops with longer duration can thus take up to 10 years for the development of a new variety. “Speed breeding” is a concept that includes a variety of techniques, some of which are guided by the crop and the trait of interest, that can significantly shorten breeding times and improve selection efficiency. These include doubled haploidy (doubling the number of chromosomes normally occurring in the mature germ cells), rapid cycling, shuttle breeding, molecular marker-assisted selection and genomic selection, all of which are used in the seed industry to accelerate the pace of breeding programs. These techniques, combined in recent times with “omics” technologies (technologies that address genome at the organism level or genomics, at the transcript/RNA level or transcriptomics, at the protein level or proteomics, at the metabolite level or metabolomics and at the phenotype/characteristics level or phenomics) and Big Data, have the potential to improved breeding efficiencies at increasingly affordable costs.

Impacts of mutation breeding on food security and income: Some recent examples

Induced mutations or variants have been routinely used in plant breeding for the improvement of a variety of traits, including increased yield, climate-change adaptation (tolerance to drought, heat, salinity etc.), resistance to transboundary diseases, and others. Much success has been achieved in crop improvement through mutation breeding in Member States of the IAEA through the technical support of the Joint FAO/IAEA Division. Mutation breeding, through nuclear techniques or chemical means, provides new genetic diversity, can be applied more easily compared to transgenic breeding, and can be used for step changes in crop improvement in countries that are not inclined, or do not have the regulatory framework, to adopt transgenic solutions.

Yield increase: Increased yield has been one of the main mutation breeding targets for many of IAEA’s Member States. In Vietnam, 20 mutant rice varieties have been released in recent years, which are grown by more than 300,000 farmers. Further, 50% of the soybean area in the country is covered by mutant varieties. In Peru, the barley mutant variety, Centenario II, covers 18% of the barely area and contributes USD 6.6MM annually, while the amaranth variety, Centenario, covers 47% of the amaranth area.

Climate-change adaptation: Mutation breeding for climate-change adaptation has mostly addressed tolerance to drought, heat and salinity. Sudan, a country that ranks fourth among the leading groundnut-exporting countries, produces 70% of the crop

in the western States of Kordofan and Darfur, which are prone to late-season drought stress. This has serious implications on groundnut pod-filling and maturation, and consequently production. A recent IAEA project that combined mutation breeding with farmer-participatory selection led to the identification of a new variety, TAFRA-1, which has shown 11% increased yields in the marginal dry areas above the prevailing local varieties. In Pakistan, four new heat-tolerant mutant cotton varieties have been identified since 2013, and these currently cover more than 25% of the 3.1 million hectares of the cotton production area in the country.

Disease resistance: Resistance to diseases is a major trait in crop plants for which genetic diversity is constantly sought, as existing resistance could break down, pathogen races can evolve, and transboundary spread can lead to extinction of popular crop varieties and seriously impact national economies. Mutation breeding has helped develop genetic variability for disease resistance in several instances. Resistance of barley to mildew developed through induced mutagenesis with X-ray was reported as early as 1942 by R. Freisleben and A. Lein. A mutant Japanese pear variety, Gold Nijisseiki, with resistance to the black spot disease, was developed in Japan in the 1990s. It combined the excellent quality of the popular variety, Nijisseiki, with resistance to the disease. A patent for its invention filed in 1992 was awarded in 1994 (US patent, USPP8529P). Disease resistance, when monogenic or the result of a single gene, is usually broken down within a short time. However, there have been exceptions, with the classical example being resistance conferred by mutation in the *ml-o* locus against all known fungal pathotypes of the powdery mildew, *Erysiphe graminis*, in barley, which has lasted a long time without breaking down.

Most recently, the disease Fusarium wilt in banana caused by the soil-borne fungus *Fusarium oxysporum* f. sp. *cubense* Tropical Race 4, that has been devastating plantations in Asia, spread to Africa in 2013, and to Latin America in August 2019. Mutation breeding efforts, through chemical mutagenesis in China, has already led to the development of a resistant banana variety, a breakthrough that holds promise for combating this disease with mutagenesis.

Nuclear and isotopic techniques in soil, water and nutrient management

Soil, water and nutrients are key natural resources that are critical for food security and sustainable development. Each year approximately 5–7 million hectares of surface soil (soil in the top 20 cm) (including nutrients) are lost through inappropriate soil management (FAO, 2019). Meanwhile more than 70% of the global water use is consumed for crop production and half of this is wasted through inappropriate fertilization and irrigation practices, polluting surface and groundwater. Climate change, with extreme weather events such as droughts and flooding, further exacerbate the issues. Improving the management of these resources through climate-smart agricultural practices can enhance food productivity and environmental sustainability.

Nuclear and isotopic techniques offer comparative advantages over conventional methods, as they often are more accurate, precise and specific, allowing effective assessment of the impact of climate change on agriculture and vice versa, so that technologies for adaptation and building resilience to climate change and the improvement of agriculture practices for potential mitigation can be developed.

In the following paragraphs, the unique role of nuclear and isotopic techniques that include the use of radioactive and stable isotopes, in soil, water and nutrient management is briefly discussed. Included are impact stories and case studies to showcase how these techniques can provide information essential to developing strategies and optimize soil-water-plant-nutrient management practices to increase crop productivity and foster environmental sustainability.

Integrated soil fertility and crop nutrition management

With the rapid population increase and the need for sustainable agricultural intensification in many parts of the world, improving soil fertility, nutrient use efficiency, and crop nutrition, is essential to enhance crop productivity and food security.

The stable isotope of nitrogen-15 (^{15}N) was discovered in the 1920s and the advantage of using it in agriculture, for instance for the determination of N use efficiency, has been recognized and applied very early on. It is estimated that half of the global application of 120 million tons of N fertilizer, which is worth billions of dollars, are not taken up by plants. Such N use efficiency study could be carried out because it is possible to label normal N fertilizer with ^{15}N isotopes. Hence the ^{15}N technique allows tracing N-fertilizer movement throughout the plant (IAEA, 2001). By identifying the pathways of the nutrient flow, substantial information can be drawn for N utilization efficiency. This allows for the development of integrated and sustainable soil and plant nutrient management practices for increasing soil fertility and crop yields.

The ^{15}N technique, when coupled with efficient Rhizobium bacterial strains, has been used to quantify the amount of N fixed through the process of biological N fixation (BNF), which is an alternative source to inorganic N fertilizer for crop growth (Chalk and Craswell, 2017). The N fixed by legume plant nodules not only promotes growth of the host plant but also leaves more N in the soil for subsequent crops. Major grain legumes have been estimated to fix approximately 11.1 million metric tons of N per year from the atmosphere in developing countries, as measured by the stable ^{15}N isotope methodologies (Hardarson et al., 2003). This helps reduce the need of inorganic N fertilizers for many poor farmers.

In tropical acid soils, isotopic and associated techniques such as the carbon-13 (^{13}C), phosphorus-32 (^{32}P) and phosphorus-33 (^{33}P) techniques have been of assistance to: (i) identify crop genotypes that are tolerant to aluminum toxicity and phosphorus (P) deficiency that are common in tropical acid soils; (ii) assess the effectiveness of a range of P fertilizers in providing P for crop requirements and (iii) quantify the enhancing effect of conservation tillage on soil quality.

Improving water use efficiency and water quality

Agricultural production and food security are highly dependent on the availability of water. Improving agricultural water management and its quality is key to sustainable and productive agriculture. Hence accurate measurement and assessment of the spatial and temporal dynamics of soil water content is crucial. This is the first step towards tackling agricultural water management problems.

Nuclear and isotopic techniques also play an important and unique role in providing information essential for developing strategies to improve agricultural water use efficiency (WUE), and hence in providing solutions to mitigate the increasing water scarcity. For example, the variation in the composition of water isotopes (^{18}O and ^2H) in the water vapour surrounding plants makes it possible to separate the process of evapotranspiration into individual component of plant transpiration and soil evaporation, so that measures can be taken to minimize the evaporation component to improve WUE. The soil moisture neutron probe is an accurate device for irrigation management—especially under saline conditions and cracking soil to improve irrigation management (IAEA, 2008). The newly established cosmic ray neutron sensor (CRNS) (Desilets et al., 2010; Wahbi et al., 2018) has been shown to be suitable for providing real-time and accurate landscape soil-water content measurements, making it ideal for long-term monitoring in agricultural ecosystems to aid in agricultural water and nutrient management decisions at larger scales (20 ha in area). This includes drought and flood forecasting, as it provides large scale data on saturation of near-surface soil layer, which is controlling the partition of infiltration and runoff. The principle employed here is to focus on fast neutrons onto the soil. If water is encountered, the neutrons are slowed down and easily registered by a thermal neutron detector.

The water stable isotopes (^{18}O and ^2H) are also suitable to evaluate groundwater sources and to quantify groundwater recharge rates as each water sources has unique water isotope composition, which remain constant as long as there are no phase changes along the flow-path. By knowing the origin and age of the water, sustainable groundwater extraction rates can be determined to avoid over-exploitation of aquifers. Isotopic compositions of water can furthermore be used to trace the return and loss of irrigation water, as evaporation changes the isotopic ratio. The use of ^{18}O and ^2H is therefore an important part of agricultural water management, allowing the identification of water sources and the tracking of water movement and pathways within agricultural landscapes as influenced by different irrigation technologies, cropping systems and farming practices. It also helps in the understanding of plant water use, including its efficiency, quantifying crop transpiration and soil evaporation allowing farmers to devise strategies to improve crop production, reducing unproductive water losses and minimizing land and water degradation (IAEA, 2017).

The stable isotope ratio of nitrogen in nitrate is distinct in different nitrate sources, for example synthetic fertilizer ($\delta^{15}\text{N} \approx -1\text{‰}$ to $+2\text{‰}$), animal waste or sewage ($\delta^{15}\text{N} \approx +8\text{‰}$ to $+16\text{‰}$) (Wassenaar, 1995), making it possible to trace the origin of nitrate and, hence, allows distinguishing between natural and synthetic inputs. Combined with other isotopic tracers such as boron and modeling approaches, it is further possible to distinguish between sewage, manure or mixed nitrate sources. Changes in the isotopic compositions of nitrate over time can also trace and quantify nitrification processes, which are important to evaluate the residence time and leaching of nitrate, and its natural remediation capacity within the soil column and groundwater.

Soil erosion control

Soil erosion by water results in an irreversible loss of fertile topsoil, reduction of soil productivity, damage of infrastructure, pollution of water resources and accelerated sedimentation in water reservoirs and harbors. Erosion leads to soil disruption and aggregate breakdown and hence, partial mineralization of soil organic carbon (SOC) and CO_2 release. The annual global cost of soil erosion and its associated downstream impact have been estimated at US \$400 billion (FAO, 2017). Accurate information on the extent and magnitude of soil erosion affecting agricultural land to strengthen soil conservation strategies is becoming crucial.

New techniques for evaluating soil redistribution processes are available to complement conventional methods. A great advance has been achieved due to the development and refinement of erosion assessment methods using specific radionuclides. Four of them are called fallout radionuclides (FRNs), because they are deposited in soil via atmospheric fallout from nuclear weapons testing, and are used as soil erosion tracers. The most commonly used radiotracer is the anthropogenic medium-lived ($T_{1/2} = 30.2$ years) cesium-137 (^{137}Cs) that originates mostly from past atmospheric nuclear weapon tests and nuclear power plant accidents (Zapata, 2002). Similar application is possible using long-lived isotopes of plutonium (i.e., $^{239} + ^{240}\text{Pu}$) originating also from the previous atmospheric nuclear weapon tests. Further information on long-term sediment budget and short-term erosion events can be gained by assessing the distribution of natural radionuclides such as the medium-lived ($T_{1/2} = 22.3$ years) geogenic lead-210 (^{210}Pb) and short-lived ($T_{1/2} = 53.3$ days) cosmogenic beryllium-7 (^7Be), respectively (Meusbürger et al., 2018).

The principle to investigate soil erosion and sedimentation is similar for all four FRN tracers. When deposited on the soil surface, they are strongly bound to soil colloid particles (clay and organic matter) in the uppermost soil layer and they move in the environment mainly by mechanical and physical processes such as tillage and soil erosion. Therefore, if the soil surface is eroded, the level of FRNs is significantly reduced. In deposition areas, the quantity of FRN increases. Erosion or deposition processes can be precisely estimated by comparing the level of selected FRN at a studied site to established inventory at a reference site that was undisturbed and represents the original fallout. The estimates of soil redistribution rates can then be derived using specific FRN conversion models.

Due to the different half-lives of these radionuclides, the combined use of FRNs (i.e., ^{137}Cs and ^{210}Pb) have been used, for instance, to estimate medium and long-term soil erosion rates and to establish sediment budgets in agricultural fields under Mediterranean climatic conditions in Morocco and for studying the effects of land use and the shift in tillage systems, i.e., from conventional to no-tillage in Chile. Moreover, in Madagascar the use of ^{137}Cs and ^{210}Pb highlighted that traditional terrace systems could

reduce soil erosion by 40%. On the other hand, the short-lived ^7Be has been used for evaluating the impact of short-term (up to 6 months) changes in land use practices and the effectiveness of soil conservation measures for ensuring sustainable management (Mabit and Blake, 2019).

In the last decade, an innovative method for investigating soil degradation processes and especially for establishing the origin of sediment emerged. It is based on compound-specific stable isotope (CSSI) analysis of carbon-13 (^{13}C) in targeted biomarkers such as fatty acids. Indeed, plant communities “label” the soil where they grow by exuding organic biomarkers, and plant species produce a similar range of organic compounds, but with different ^{13}C signature (IAEA, 2019).

FRNs and more recently the CSSI techniques have been tested and validated in various IAEA Coordinated Research Projects (CRPs) and the findings disseminated through the Technical Cooperation Program to more than 70 IAEA Member States to improve the effectiveness of their soil conservation strategies (Mabit et al., 2018).

Greenhouse gas emissions from agriculture

The rapidly changing global climate due to the increased emission of anthropogenic greenhouse gases (GHGs) is leading to an increasing occurrence of extreme weather events such as droughts, floods and heat waves. It is estimated that agricultural activities, deforestation and draining wetlands contribute to some 25% of the total GHGs emission. Agricultural emissions are generally linked to the management of agricultural soils, livestock, rice production and biomass burning.

The three major GHGs include carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O). The major natural sources of CO_2 include ocean-atmosphere exchange, respiration of soils (microbial respiration) and plants, and volcanic eruption; while the anthropogenic sources include burning of fossil fuel (coal, natural gas and oil), deforestation, and the increasing conversion of peat-land and forest land for agriculture. Natural sources of CH_4 emission include wetlands and oceans. Paddy fields used for rice production, livestock production systems (enteric emission from ruminants), landfills, and the production and use of fossil fuels are the main anthropogenic sources of CH_4 .

Nitrous oxide, in addition to being a major GHG, is also an ozone-depleting gas with the highest global warming potential of 298 times that of CO_2 over a 100-year time period. Anthropogenic emissions of N_2O occurs mostly through agricultural and other land-use activities including the intensification of agricultural and other human activities such as increased use of synthetic fertilizer (119.4 million tonnes of N worldwide in 2018), inefficient use of irrigation water, deposition of animal excreta (urine and dung) from grazing animals, excessive and inefficient application of farm effluents and animal manure to croplands and pastures, and management practices that enhance soil organic N mineralization and C decomposition. Over the last decade the rate of N_2O increase was equal to $0.93 \text{ ppb year}^{-1}$.

The role of individual factors controlling the occurrence and rate of the key N transformation processes, such as denitrification and nitrification are uncertain. Nitrification results in ammonium (NH_4^+) being converted to nitrate (NO_3^-) under aerobic conditions, while denitrification is the reduction of NO_3^- to N_2 under anaerobic conditions. Nitrifier-denitrification occupies the niche between nitrification and denitrification and occurs as oxygen concentrations approach an anaerobic status. Under these conditions nitrifiers actually convert nitrite to N_2O and N_2 instead of nitrate.

These GHGs, CO_2 , CH_4 and N_2O , derived from various sectors, play a major role in regulating earth's temperature (Fig. 3). Without GHGs in the atmosphere, the average global soil surface temperature would be about -19°C , compared to the present values of 14°C (Karl and Trenberth, 2003; NASA 2009).

Recent data by the UN Intergovernmental Panel on Climate Change (IPCC) clearly show that anthropogenic emissions of GHGs are at the highest in history (IPCC, 2014). Since 1900, earth's average surface air temperature has increased by about 0.8°C , with much of these increases taking place since the mid-1970s. (Fig. 4).

Several non-isotopic approaches exist for measuring GHGs from agricultural soils; however, some of the problems with field GHG flux measurements are the large spatial variability of gas fluxes, and the high and often unpredictable temporal changes of fluxes. In addition, these non-isotopic techniques do not identify the sources (soil-N or fertilizer-N) nor the microbial process that generate N_2O emission in soil. Contrary to non-isotopic techniques, the use of ^{15}N stable isotope technologies offer the best choice for precise measurement of N_2O and N_2 and for identifying the exact sources of N_2O production.

Microbiologists have utilized the new possibilities that ^{15}N can offer, as it is now possible to quantify the turnover rates of individual processes in the N cycle based on dilution principles. Moreover, ^{15}N allowed for the first time the development of techniques to quantify the loss of N_2 against a huge atmospheric N_2 background. Also, the identification of which processes contribute to total N_2O emissions is unthinkable without the use of advanced ^{15}N tracing techniques (Müller et al., 2014). Various microbial processes (nitrification, denitrification, co-denitrification and organic N conversion to nitrite) produce N_2O . The two atoms of the N_2O (NO and N) molecule can be labeled with ^{15}N differently (i.e., alpha and beta positron). Therefore, the analysis of the two N atoms in ^{15}N labeled provides information on the exact microbial process that produces N_2O . This is commonly referred to the site preference (SP) which can be analyzed by modern analytical techniques (e.g., Isotope Ratio Mass spectrometers (IRMS) or Cavity Ring Down Spectroscopy (CRDS)) and therefore providing information on the origin of the N_2O molecules. There is a wealth of information we can obtain from using diverse isotopic approaches based on ^{15}N or ^{18}O labeling, but also based on natural abundance techniques that take advantage of the different metabolism with which for instance N_2O is produced. This, ultimately, provides us with the tools to identify emission pathways and in turn provide information on effective mitigation techniques.

Nuclear emergency and response affecting food and agriculture

Accidental releases of radionuclides to the environment (Miller, 2021) and their subsequent transfer to the food chain is a dynamic process that varies temporally and spatially across agricultural landscapes. Quickly identifying affected food production areas using up-to-date information of soil, water and plants are necessary for preventing potentially contaminated products from reaching consumers. This is especially the case for large-scale emergencies, whereby efficient management of big and diverse datasets determines the speed and quality of response.

Traditional processing of radioactive contamination data impacts both response times and accuracy as they are performed manually and not centralized. Developments in Information Technology-Decision Support Systems (IT-DSS) tools and algorithms allow for improved real-time management of large volumes of data and integrated decision-making support.

The modern IT-DSS provides clear visual aid for improving response capabilities. Examples include the potential to graphically represent the collection phase (maps showcasing status of sample collection or analysis), the analysis/validation phase (maps showcasing radioactivity concentration/deposition) and the decision-making phase (dashboard assisting in suggesting food restriction sites). Food contamination maps can be made available immediately, and the ability to visually assess real-time data helps weigh cost and benefits of possible response scenarios. These decision-making support functions increase the capacity of stakeholders to focus on the most important matters at hand—ensuring food and consumer safety. The IAEA recently developed an online Decision Support System for Nuclear Emergencies Affecting Food and Agriculture (DSS4NAFA) (Lee Zhi Yi and Dercon, 2019). DSS4NAFA is a cloud-based decision support system to manage large volumes of spatial and temporal data, real-time information processing and visualization, and enhanced aid to response actions and decision-making in case of a nuclear or radiological emergency affecting food and agriculture.

Future developments in innovative technologies used for response processes affecting food and agriculture include the use of artificial intelligence and machine learning to automate response processes and optimize resource-use efficiency.

Summary

Nuclear and isotope applications have played a key role in crop production over the last six decades in many countries, especially the Member States of the IAEA. Genetic diversity introduced through mutation breeding into more than 220 plant species using mostly physical mutagens (γ -rays) has led to the development of over 3000 improved crop varieties globally as recorded in the IAEA Mutant Variety Database. A majority of these are food crops contributing to food security of many developing nations. Harnessing the genetic potential of improved crop varieties require optimal agronomic practices including soil, irrigation water and nutrient management. Nuclear and isotope techniques have facilitated the determination of soil nutrient levels to plan optimal fertilizer rates, improve water and irrigation management, and the identification of the prevalence of soil erosion and redistribution to enable better landscape management. More recently these techniques are also being used for determining the rate and type of greenhouse gas emissions from agricultural soils, information that can be used to optimize farm management practices for reduced emissions. Finally, the Joint FAO/IAEA Division has also developed decision support tools to nuclear emergencies affecting food and agriculture.

Introduction

The global human population has almost doubled over the last 40 years, with the major proportion of the increase occurring in developing countries. Human population is expected to approach 10 billion by 2050 (United Nations, 2019). Today, one billion of the world's people face hunger and, therefore, are "food insecure" (FAO, 2019). Governments, international organizations, research centers and non-government organizations (NGOs) are placing individual and coordinated efforts to overcome this overwhelming situation (Nissanke and Thorbecke, 2007), for example, the 2030 Agenda for Sustainable Development Goals (FAO, 2018).

Livestock and crop production are major elements of support to the economy of most developing countries and provide livelihood for a significant proportion of the population. However, this production is highly dependent on the rural population. According to FAO, nearly 25% of the gross domestic product (GDP) derives from agriculture in many of the least developed countries. Furthermore, farmers in Latin America generate more agriculture value added than in other developing regions.¹

The role of livestock in developing countries is complex and significantly different from the situation in industrialized countries. Livestock are multi-purpose and contribute in many other ways to the socioeconomic welfare of people. Animals are valued for their hides and skins, and they provide manure, which helps to replenish soil fertility. For many rural farmers, livestock are a "living bank" and serve as a financial reserve during periods of economic distress. The development of the livestock sector would not only help developing countries to achieve self-sufficiency in animal products, but also prevent the migration of rural poor to urban areas in search of supposed economic benefits.

Nuclear and nuclear-related techniques

Nuclear applications provide added value to conventional approaches in addressing a range of agricultural problems and issues, including crop and animal production, animal disease diagnosis and control, insect pest control, food safety and sustainable use of natural resources. Nuclear and nuclear-related technologies are useful tools in research and development. They provide the basis to formulate appropriate management strategies for improving livestock productivity (Makkar, 2008; Odongo et al. 2010; Viljoen and Luckins, 2012).

Animal nutrition

In developing countries, livestock are fed mainly on low quality roughages, including natural grazing and agro-industrial by-products, which usually are seasonally dependent (Galyean and Hubbert, 2014). Research done using ¹⁴C, ³²P and ¹⁵N labeled material to measure the efficiency of rumen fermentation (chewing the cud) in cattle and buffalos fed the most commonly available feeds, along with data obtained from conventional methods (e.g. digestibility, rate of passage and feed intake) has allowed for the establishment of optimal combinations of feeds for use as supplements to available pasture and grazing (Leng and Nolan, 1984; Cantalapiedra-Hijar et al., 2015) (Fig. 1).

In animal nutrition research and feeding practices, several stable isotope and other radio-isotope techniques have definite benefits over conventional techniques: (1) carbon tracers (¹⁴C) can be used to develop models for the description of relationships between purine absorption and purine derivative excretion in urine (Liang et al., 2004), (2) infusion of ¹⁴C labeled acetic and propionic acid are being used to estimate volatile fatty acid production rates (Leng, 1970), (3) nitrogen (¹⁵N) labeled ammonium bicarbonate and ammonium chloride can be used to study microbial degradation of poor quality fibers, microbial mass, utilization of non-protein nitrogen, urea recycling, microbial protein synthesis and amino acid interconversions in rumen (Cantalapiedra-Hijar et al., 2015), (4) the rate of microbial protein synthesis is determined by phosphorus (³²P, ³³P), ¹⁴N or ³⁵P incorporation in rumen microorganisms (Kaswari, 2004), (5) cobalt (⁵⁸Co), chromium (⁵¹Cr) labeled forages (consumed plant materials) are used for passage rate determination (Uden et al., 1980), and (6) ¹⁴C/¹³C labeled sodium bicarbonate infusion techniques are used for estimating carbon dioxide production in the rumen (Duin et al., 2016). Additionally, methane emission by ruminants can be estimated by isotope dilution using either tritium (³H) or ¹⁴C labeled methane (Follet et al., 2001).

In pasture-based production systems, animals are highly selective of plants and parts of the plant that they eat and therefore the consumption and nutritional value of the total intake is hard to determine with any reasonable precision. However, conventional

¹<http://www.fao.org/3/i2490e/i2490e01c.pdf>.

Fig. 1 Evaluation of nutritional value and efficient use of locally available feeds.

chemistry analysis and stable carbon isotope composition ($\delta^{13}\text{C}$ of n-alkanes)² can provide reliable data related to the nutritional value of those feeds, dry matter intake and plant proportions (Dove and Mayes, 2006). These data, in conjunction with information provided by the near infrared reflectance spectroscopy (NIRS), can allow the design of diets and supplements required to improve animal productivity under grazing conditions.

Animal reproduction

Low fertility is often identified as one of the primary constraints to livestock production. The monitoring of reproductive hormones, especially progesterone, through radio-isotopic techniques such as radioimmunoassay³ (RIA) has provided enormous advantages for a better understanding of the reproductive physiology of livestock species, for monitoring ovarian cyclicity, identifying anoestrus (animals without signs of oestrus for long periods) and non-pregnant females, and in assisting artificial insemination (AI) centers and AI service providers on management and detecting human errors in AI (Fig. 2) (Garcia and Edqvist, 1990; Rajamahendran et al., 1993; Garcia et al., 2001). Progesterone RIA can also be used for detecting non-pregnancies in cows as progesterone values are supposed to be very low or not detectable at 22–24 days of the oestrus (day of service).

Fig. 2 Monitoring post-partum ovarian activity through radioimmunoassay (RIA) progesterone analysis.

²Isotopic signature, a measure of the ratio of stable isotopes ^{13}C : ^{12}C .

³Nuclear technique based on a competitive binding, where a radioactive antigen (in this case a radiolabelled progesterone) competes with a non-radioactive antigen (the progesterone hormone in the milk or blood sample) for binding sites in specific antibodies (e.g. against progesterone). The radioactivity of the reaction is measured in a gamma counter.

Novel uses of nuclear techniques for research purposes involves the identification of potential candidate protein biomarkers for early pregnancy detection by day 16 after AI. To identify these biomarkers, embryos are being experimentally cultured in vitro with radioactive labeled amino acids (e.g. ^{35}S), which will then be integrated into proteins synthesized by the conceptus. This approach offers the possibility of tracking de novo protein synthesis, and consequently proteins produced by the conceptus that could be used as early pregnancy biomarkers. These proteins, once identified, could be detected in maternal blood by RIA or other nuclear-related technique. RIA is already being used for determination of Pregnancy Associated Glycoproteins (PAG) concentrations in blood and in milk on days 35–42 after service (Ayad et al., 2007); and changes in micro-RNA in the bloodstream and milk may identify pregnancy in cattle as early as 24 days after service (Ioannidis and Donadeu, 2016).

Animal genetics

Genetic improvement of farm animals for productivity of milk, meat and fiber is traditionally based on identifying the high-performance animals. With the recent advances in nuclear derived genomic technologies, it is now possible to speed up the process of genetic improvement, by estimating breeding value of animals as soon as they are born, using the variations in an array of DNA markers spread across its genome (Hayes et al., 2009). These DNA markers have been identified through a range of nuclear-related approaches. Radiation hybrid (RH) mapping is a method for producing high resolution maps that can be used for integrating linkage maps and can serve as a link across species for comparative mapping (Perelman et al., 2018). Genome assemblies of major livestock species and humans have been fully developed, and other important farm species like the camel and the alpaca are in the process (Fig. 3).

Nuclear, nuclear-derived, and molecular techniques for genetic characterization of indigenous and/or locally adapted animal species, populations and breeds, and for the identification of genes and markers related to productive (i.e. milk, meat, wool and fiber) traits and those related to functionality, such as resistance to diseases (e.g. gastrointestinal parasitism in ruminants), are becoming important tools in understanding biology and enhancing genetic selection programs in cattle and small ruminants (sheep and goats). Genomic data of performance-recorded animals enable breeders and farmers to relate production traits with not only parentage, but also genetic admixture of animals when animals are a hybrid of multiple breeds, which is commonly the case in peri-urban dairy production systems. Such analyses can facilitate the identification of superior (both genotypically and phenotypically) crossbred genotypes for subsequent mating with artificial insemination.

Animal health

Nuclear and nuclear-related technologies have played an important role in animal health, particularly in relation to disease diagnosis and characterization of pathogenic organisms. Although many of the tests using radioisotope labels have been replaced, the new tests that have been developed rely in their inception on the radiolabeling methods that preceded them, so they are still very much nuclear-related (Viljoen and Luckins, 2012).

Vaccines

The control and prevention of diseases are of utmost importance, and vaccines play major roles. Vaccination is a cost-effective way of controlling animal diseases; however, there is a large variation in their efficiency, immunogenicity, shelf-life and storage requirements (Centers for Disease Control and Prevention, 2015).

Gamma irradiation of pathogens seemed to be a viable alternative nearly 40–50 years ago, but due to limitations in culture techniques, lack of molecular understanding of the genetics involved and limited irradiation sources avoided further research on this (Bain, 1999). Recent findings show that irradiation affects the ability of pathogens to replicate; therefore, producing sustainable immunity but preventing the occurrence of infection in the host. Current research using ^{60}Co and X-rays is showing flattering laboratory results for irradiated vaccines against some bacteria (Ahmed et al., 2015), parasites (*Haemonchus contortus*, *Salmonella gallinarum*) (Ammar et al., 2014) and viruses (avian influenza) (David et al., 2017).

Stable isotopes

The emergence of highly pathogenic strains of Influenza A virus (AIVs) in birds has been of considerable concern over the last few years as AIVs threaten animal health, livestock productivity and food security, and they can also evolve into dangerous human pathogens. In cases of outbreaks, millions of chickens are killed and many more are destroyed to control the spread of the disease affecting the availability of poultry meat in the country or region. Tracing the movements of migratory birds in relation to where they originated as well as their stopover points in their migration between breeding and non-breeding grounds render a better understanding of their role in spreading AIVs and facilitate its control (Fig. 4). A suitable technique to trace migrants is based on stable isotope (SI) signatures of tissues of birds, e.g. deuterium, especially those in feathers, as there is a strong correlation between levels of these SIs in the environment and the concentration of the same SIs in avian tissues (Meier et al., 2017). In order to improve the resolution of the migration patterns through spatial isoscapes,⁴ other isotopes may be included such as carbon (^{13}C) nitrogen (^{15}N), oxygen (^{17}O or ^{18}O) or sulfur (^{33}S , ^{34}S or ^{36}S) (Glew et al., 2018).

⁴The word isoscape is derived from isotope landscape. The IAEA defines the isoscape as “gridded isotopic landscape.” Please see http://www.naweb.iaea.org/naweb/ih/IHS_resources_rcwip.html.

Goat Radiation Hybrid Map Development

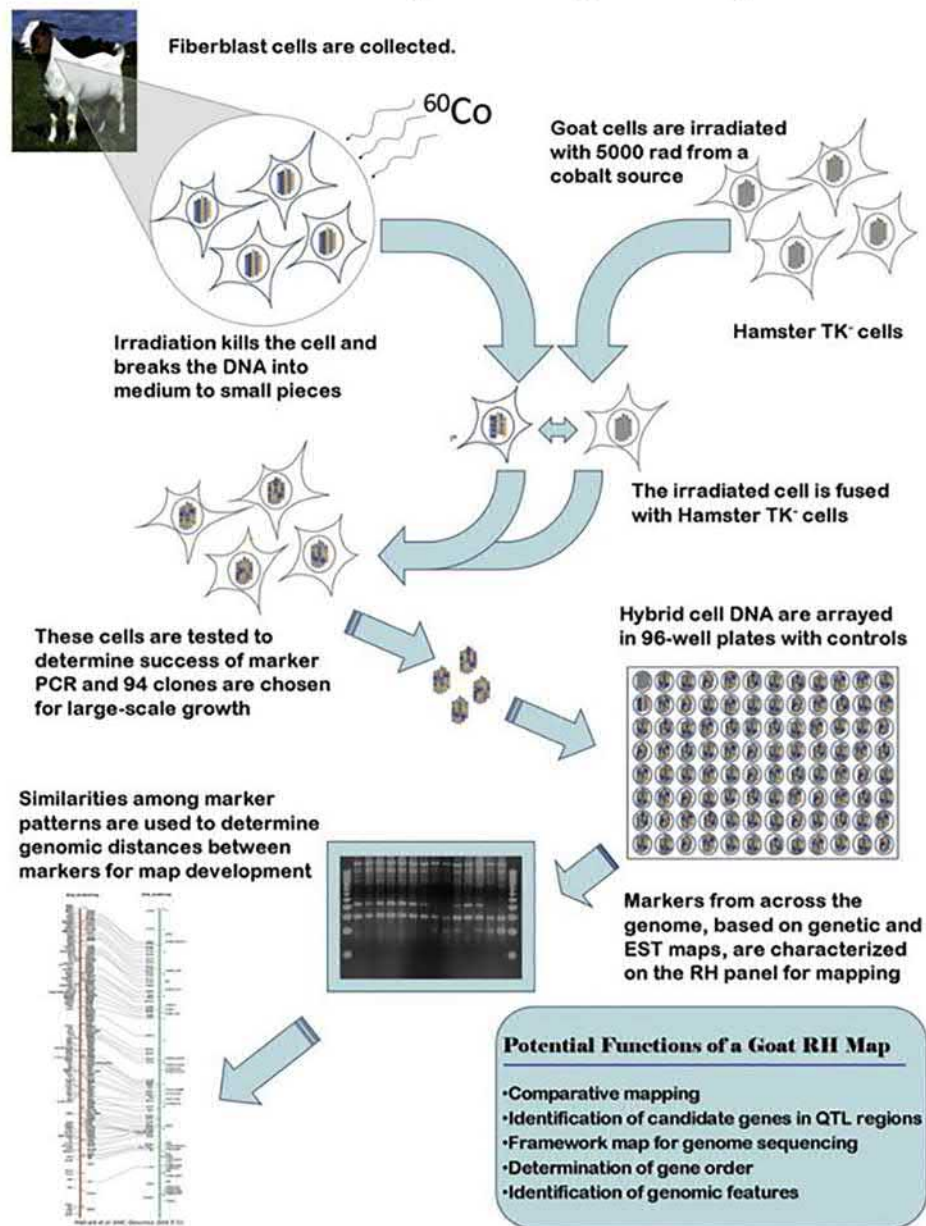

Fig. 3 Schematic overview of goat radiation hybrid map development.

Fig. 4 Diagram showing the relationship of the stable isotope's role on the identification of migratory paths of wild waterfowl birds and detection of avian influenza virus.

Disease diagnosis

Isotopic techniques that included the use of ^{75}Se , ^{32}P , ^{125}I , and ^{35}S isotopes have enabled high levels of sensitivity and specificity for the detection of antibodies against animal pathogens (Rodák et al., 1981). The present-day extensive use of enzyme immunoassays (ELISA) and molecular methods (e.g. PCR) for diagnosis and characterization of animal pathogens has its origins in the use of isotope-labeled antigens and antibodies. ELISA is a technology used for detection of the antigen (pathogen) or antibodies induced by specific pathogens in the body of the host, where the isotope has been replaced by an enzyme⁵ that can be measured through color changes in the assay (Wright, 1995; Ma et al., 2011; Viljoen and Luckins, 2012). The PCR and the cyclic sequencing have their origin in purely nuclear techniques, where individual nucleic bases were labeled using radioactive isotopes, followed by transferring the signal from agarose gel⁶ onto a photographic film (Pestana et al., 2010). Although in many cases, due to safety reasons, the isotopic labeling has been replaced by enzymes (ELISA) or fluorophores (PCR), it has still major advantages over alternative labeling systems, as it does not affect the chemistry of the reactions and is, therefore, considered as the reference standard.

Nuclear and nuclear-related techniques, including immunological and molecular techniques, are highly valuable for control and prevention of major emerging transboundary animals and those of veterinary public health importance (Viljoen and Luckins, 2012). Main livestock and poultry diseases of interest in developing countries, some of them of zoonotic nature (affecting humans) include the highly pathogenic avian influenza (HPAI), foot-and-mouth disease (FMD), peste des petits ruminants (PPR), Rift Valley fever, brucellosis, contagious bovine pleuropneumonia (CBPP), Middle East respiratory syndrome (MERS), Newcastle disease, classical/African swine fever (CSF/ASF), lumpy skin disease (LSD), bluetongue, pox viruses and trypanosomiasis, as well as gastrointestinal parasites (i.e. *Haemonchus* sp. and *Fasciola* spp.). Moreover, several multi-pathogen detection systems for cost-effective syndromic surveillance and rapid differential diagnosis have been or are being developed and validated (Settypalli et al., 2016). Considering the variety of pathogens, differences among tests and chemicals involved, as well as the ample differences in expertise and infrastructure among laboratories, standardization of the methods is of great importance. The use of standard operation procedures (SOPs) and, if possible, the ISO accreditation of national disease diagnostic laboratories to build self-confidence on sample analysis and reporting is strongly recommended. The Veterinary Laboratory (VETLAB) Network, driven and supported by the IAEA involves veterinary diagnostic laboratories from 49 African and 19 Asian countries and it is expanding to other continents to facilitate sharing of expertise, data, information and material, development and harmonization of diagnostic methodologies, and supporting access to sequencing services and for international accreditation (<https://www.iaea.org/services/networks/vetlab>).

As an example of success can be mentioned the eradication of rinderpest (the cattle plague), where the ELISA kits were of high value for the monitoring of animals vaccinated and those carrying the disease. Rinderpest was for centuries a major cause of famine and poverty. In 2011 the FAO and OIE declared the disease officially eradicated from the world. This great achievement comes 30 years after the WHO declared that smallpox was eradicated, the only other viral disease to have been eliminated from the world. The estimated net annual economic benefit for the African region is at least US\$ 1 billion per year.

Area-wide integrated pest management (AW-IPM)

The publication in 1962 of Rachel Carson's "Silent spring" (Carson, 1962) was the start of growing concerns with respect to the massive use of broad-spectrum insecticides for the management of insect pests. These alarms have in the past decades resulted in increased demands for alternative methods of insect pest control that are not only effective but friendly or neutral to the environment. The concept of integrated pest management (IPM) offers a strategic approach to solving pest problems in an ecosystem context while taking into consideration any possible negative impact on human health and the environment (Brader, 1979). The IPM has remained the dominant paradigm of pest control in the last decades (Hendrichs et al., 2007). Against livestock pests, IPM programs can be implemented on a localized, herd-by-herd or field-by-field basis or through the management of entire insect populations in a delimited geographical area, i.e. area-wide IPM (Hendrichs et al., 2007; Vreysen et al., 2007; Klassen and Vreysen, 2020).

In a localized approach, individual livestock producers or farmers manage insect pests independently, without investing efforts to coordinate, collaborate or having to obtain the consent of their neighbors. The approach ignores pest individuals that frequently migrate into the treated area from infested areas in the untreated surroundings (Hendrichs et al., 2007). Localized pest control does not require a long-term commitment to a well-funded centralized management structure but relies on re-active interventions triggered when a pest population reaches a certain threshold and mostly rely on insecticide applications (Klassen and Vreysen, 2020).

Using simple mathematical population models, Knipling (1972, 1979) showed that small fractions (below 10%) of an insect pest population left uncontrolled can drastically nullify the benefits of suppressing a pest population in a large area (Fig. 5). These small foci or refugia of relic insect populations constitute permanent and prolific sources of immigrants into the suppressed or eradicated areas. The central paradigm of area-wide control or total population management recognizes this need to address all foci/refugia from which recruits can invade suppressed or pest-free areas (Bouyer and Vreysen, 2018). The approach also takes into consideration the movement of livestock as a host of the pest.

⁵ELISA has a similar principle than radioimmunoassay (RIA). In this case, an enzyme is used instead of radiolabelled isotope for the binding competition and the gamma counter is replaced by an ELISA reader where the change in color depending of the amount of substrate (e.g. antibodies against specific pathogen) is measured.

⁶Agarose is a polysaccharide. Agarose gel is a three-dimensional matrix formed of helical agarose that is used to separate DNA fragments according to their size.

Fig. 5 Results of a model that shows the outcome of neglecting to suppress a small fraction of a pest population in an agroecosystem versus the effect of uniformly suppressing the entire pest population. Left: 10% of the population is untreated, and in four generations it produces a large number of individuals, while the 90% of the population that is treated declines. Right: Entire pest population in the agroecosystem is suppressed uniformly, and its numbers decline from generation to generation. Adapted from Knipling EF (1972) Entomology and the management of man's environment. *Austral Entomology* 11: 153–167.

Area-wide Integrated Pest Management (AW-IPM) efforts (1) focus on preventive pest management where action is taken before the pest population reaches damaging levels (preventive approach), (2) address the entire pest population throughout the ecosystem, (3) require several years of planning and an organization dedicated exclusively to the control effort, and (4) use advanced technologies such as geographic information systems (GIS), global positioning system, remote sensing and aerial release techniques (Klassen and Vreysen, 2020).

In some programs, political or financial pressures have sometimes resulted in starting an operational program without detailed knowledge about the biology, ecology and population dynamics of the targeted pest population. To avoid embarking on operational activities without sound baseline data, a phased conditional approach (PCA) should be followed (Bouyer et al., 2020). This requires that progressing to the next phase is conditional upon completion of all or most of the activities in the previous phase. Although the different phases of the PCA can vary with the target species, for tsetse flies the phases are: (1) training and commitment of all stakeholders, (2) baseline data collection and feasibility studies, (3) pre-operational activities and (4) operational activities (Vreysen et al., 2020).

The sterile insect technique (SIT)

In the 1930s, Dr. E. F. Knipling of the USA conceived the concept of managing economically important insect pests by manipulating their reproductive capacity. Knipling speculated that, if an efficient method could be found to sterilize insects, the release of large numbers of sterile males might be used to introduce sterility in the native insect pest population. Initial laboratory experiments in the 1950s showed that male and female New World screwworm flies, *Cochliomyia hominivorax* (Coquerel), could be sexually sterilized by exposure to X-rays (Bushland and Hopkins, 1951) or gamma rays (Bushland and Hopkins, 1953) without impairing their survival and field competitiveness. The technique would require the mass-production of the target insect in large factories, the sterilization of the male sex, and the sustained release of the sterile males in the target area. Mating of a sterile male with a virgin female would result in no offspring. The large numbers of sterile male insects would limit the reproduction of the natural population in proportion to the ratio of sterile to fertile insects. The sustained release of sterile insects would, with each generation result in increased levels of sterility in the target population, which could eventually culminate in the elimination of the target population.

The SIT acts inverse-density dependent, which is one of its main advantages, i.e. the control effort becomes more economical and efficient as the natural population declines and increasing ratios of sterile to wild males are achieved (Dame, 1970). This is in contrast with chemical methods of killing insects that are very effective at high density pest populations, but the continued use of the same treatment will result in the same percentage effect regardless of population density (LaChance et al., 1967) (Fig. 6).

Insect pest control programs that rely on the introduction of sterility have been based mainly on induced dominant lethal mutations (LaChance et al., 1967). A dominant lethal mutation is a nuclear change, e.g. chromosome breaks in the germ cells without affecting their maturation but killing the zygote during its development (Von Borstel, 1962). During cell division, chromosome fragments are lost because they lack a centromere,⁷ which is responsible for inclusion in the daughter nucleus. This leads to

⁷A specialized structure on the chromosome, appearing during cell division as the constricted central region where the two chromatids are held together and form an X shape.

Fig. 6 Schematic representation of the sequential use of methods of suppression that efficiently decimate a pest population followed by use of the SIT, which becomes progressively more suppressive as the population declines. The term “efficiency” refers to the ease in further suppressing the population, and not to the cost of eliminating an individual pest (cost per kill). Adapted from Feldmann U and Hendrichs J (2001) *Integrating the Sterile Insect Technique as a Key Component of Area-wide Tsetse and Trypanosomiasis Intervention*. PAAT (Programme Against African Trypanosomiasis) technical and scientific series, no. 3. Rome, Italy: FAO. Available from <http://www.fao.org/DOCREP/004/Y2022E/Y2022E00.HTM>.

chromosome imbalance with the formation of dicentric chromosomes and breakage-fusion-bridge cycles during cleavage divisions in the zygote. Death usually occurs during the early divisions before the formation of the blastoderm (LaChance et al., 1967). In 95% of the eggs fertilized by sperm of irradiated male *Glossina palpalis palpalis* Robineau-Desvoidy, embryonic death occurred in the early cleavage division stages. This was then followed by lytic processes and the extrusion of the dead eggs 1–2 days after ovulation (Matolin and Van der Vloedt, 1982).

The SIT has several advantages: (1) it is non-intrusive to the environment with no adverse effects on non-target organisms, (2) it is species-specific, (3) it can easily be combined with other biological control methods such as parasitoids, predators and pathogens, (4) there is no risk of the development of resistance to the effects of the sterile males (provided that adequate quality assurance is practiced in the production process), and (5) the sterile insects cannot get established in the released areas as with other biological control programs (Vreysen, 2001).

The SIT also has its limitations: (1) the release of sterile insects is only effective and cost efficient when the target population density is low, (2) it requires detailed knowledge of the biology and ecology of the target pest, (3) the insect should be amenable to mass-rearing at a reasonable cost, (4) there is a delayed effect as the target insect is not killed but sterility introduced, and (5) the technique can only be used for those insects where the development phase that is used for the release (e.g. in most cases the adult insect or male mosquitoes that contrary to females do not transmit diseases) is not contributing to the damage. In addition, the SIT necessitates efficient release and monitoring methods, which must be applied on an area-wide basis (Vreysen et al., 2020).

The AW-IPM with a SIT component: Examples of successful implementation

Tsetse flies

Tsetse flies are the cyclical vectors of trypanosomes, protozoa that cause a disease occurring mostly in rural areas of sub-Saharan Africa where it gravely affects agro-pastoral activities. The fly infests an estimated area of 8.7 million km² where it transmits human African trypanosomiasis (HAT) or “sleeping sickness” in humans and African animal trypanosomiasis (AAT) or “nagana” in livestock. Besides the human suffering and death from sleeping sickness in certain areas, livestock production in rural areas is severely constrained by nagana (Feldmann and Hendrichs, 2001).

The first SIT-based operational program of significant size was carried out in the 1980s in the Tanga area of the United Republic of Tanzania. Two aerial applications of endosulfan⁸ (Williamson et al., 1983a) were used to suppress the targeted *Glossina morsitans* Westwood population. This was followed by the release of sterile male pupae⁹ for 15 months at a release density of 135 sterile males/km² resulting in an average sterile to wild male ratio of 1.12:1. This was too low to eradicate the population but low enough to keep the indigenous population at the 80–95% reduction level obtained after the insecticide applications (Williamson et al., 1983b).

Populations of the two tsetse fly species *Glossina palpalis gambiensis* Vanderplank and *G. tachinoides* Westwood were eradicated from 3500 km² of Guinea savannah in Sidéradougou, Burkina Faso in the 1980s. A combination of trapping techniques and insecticide-impregnated targets reduced the tsetse populations by 91–94%. Thereafter, sterile males were released at a density of 20–35 sterile males per linear km obtaining the desired sterile to wild male ratio of 10:1. The main river systems were free of tsetse flies 6 months after the start of the sterile male fly releases (Politzer and Cuisance, 1984).

⁸Chlorinated hydrocarbon insecticide of the cyclodiene subgroup, which acts as a contact poison in a wide variety of insects and mites.

⁹Complete, or holometabolous, metamorphosis is characteristic of beetles, butterflies and moths, flies, and wasps. Their life cycle includes four stages: egg, larva, pupa, and adult.

A similar approach was used to eradicate a *G. p. palpalis* population from 1500 km² of agro-pastoral land in Southern Plateau State of Nigeria. Insecticide-impregnated targets and biconical traps achieved 97–99% reduction of the fly population and this was followed by weekly releases of sterile males. In 1988, the fly was declared eradicated from the entire target area. The program demonstrated that a sterile to wild male ratio of 10:1 was a prerequisite to achieve eradication and that different habitats and different species demanded different release rates and different time frames (Oladunmade et al., 1990). Despite the successful eradication of the local tsetse populations in Burkina Faso and Nigeria, the tsetse-free status of the target zones could not be sustained, due to invasion pressure from the adjacent untreated areas. These examples exemplify the need for an area-wide approach to achieve sustainability.

The program against a *Glossina austeni* Newstead population on Unguja Island of Zanzibar (1994–97) was the first SIT-based eradication effort against a tsetse species that was implemented following AW-IPM principles. The fly population was suppressed using the live-bait technique in the agricultural areas of the northern half of the island (that had high cattle densities) and by deploying insecticide-treated blue cotton targets in the dense forested areas mainly in the south. This was followed by the aerial dispersal of sterile male flies over the entire surface area of Unguja Island, including the small offshore islands (Vreysen et al., 2000). The last indigenous *G. austeni* fly was trapped in September 1996 and Unguja Island has remained free of tsetse and AAT ever since.

In 2005, the Government of Senegal launched an AW-IPM project that aimed to create a sustainable *G. p. gambiensis* free zone in the Niayes, an area located north-east of the capital Dakar. Results of the initial phase of data collection, showed that there was only one species in the area with a limited distribution of 1000 km² (Bouyer et al., 2010), and the population was genetically isolated from the remainder of the tsetse belt (Solano et al., 2010). The impact of the removal of AAT was found to be significant with annual benefits of € 2.8 million for farmers in the tsetse-infested zone (Bouyer et al., 2014). The adopted AW-IPM strategy included suppression activities with insecticide-impregnated traps and the use of pour-on for cattle, followed by the release of sterile males to eliminate the remaining relic pockets.

New World screwworm

The New World screwworm is one of the most damaging insect pests of livestock in the tropical and subtropical areas of the western hemisphere. In 1934, 1.3 million cattle died in the south-eastern USA because of New World screwworm infestations (Dove, 1937). Between 1935 and 1937, intensive animal inspections combined with insecticidal wound treatment and good animal husbandry practices greatly reduced the incidence of wound infections, but eradication of the New World could not be achieved because wild-life and non-attended livestock served as reservoirs (Novy, 1991).

The huge economic losses result from direct reduction in productivity due to sickness and death, and from the labor and insecticide costs that are incurred from wound inspections and treatments. Gravid female screwworm flies are attracted to wounds and lay up to 400 eggs in or around the edges of these wounds. The eggs hatch and the larvae feed on the living flesh, making the wound larger and even more attractive for other females to oviposit. The larvae thrive on living warm blooded animals (including humans) and multiple infestations can kill a large cow if left untreated.

A first pilot trial using the release of sterile male New World screwworm was attempted on the Island of Curacao (Baumhover et al., 1955). Sterile males were released at a density of 300 flies per km² and eradication was achieved after only 6 months. This program led to the largest and most successful AW-IPM campaign with a SIT component ever undertaken against a major insect pest, i.e. the eradication of the New World screwworm from the southern USA, Puerto Rico, Mexico (Snow, 1988), Central America, and Panama (Wyss, 2000).

The economic benefits of this eradication program have been enormous. Although the total investment for the program has been estimated at US\$ 1300 million (over a period of almost 50 years), the estimated direct annual producer benefits are substantial and estimated at US\$ 896 million, US\$ 328 million and US\$ 87 million for the United States, Mexico and Central America, respectively (Wyss, 2000). The annual benefits for the livestock producers are, therefore, the same as the total project cost over 50 years.

In 1988, the New World screwworm was detected in the north-western part of the Libyan Arab Jamahiriya. This incursion originated most likely from the Americas although the mode of introduction remains unknown. By the end of 1990, an area of 25,000 km² was infested, which prompted the mounting of an internationally supported eradication campaign (FAO, 1992). An AW-IPM strategy to eradicate the screwworm from the infested area and to protect neighboring countries was developed that had the following components: intensive animal surveillance, insecticidal wound treatment and the sequential release of sterile insects. The sterile insects were produced at the mass-rearing facility in Tuxtla Gutiérrez, Chiapas, Mexico, and were transported by air to Libya. In February 1991, the full eradication phase was initiated with the release of 28 million sterile flies per week. By May 1991, this number was increased to 40 million/week, treating a total area of 40,000 km². Between December 1990 and October 1991, a total of 1300 million sterile New World screwworm flies were released, and in 1991 the area was declared free of screwworm (Lindquist and Abusowa, 1992).

Glossary

Aseptic Packaging Packaging foods in a sterile environment.

Becquerel One disintegration per second.

Codex Alimentarius International regulation for transboundary shipment of irradiated goods.

Curie 3.7×10^{10} disintegrations per second.

eBeam energy The energy of the electrons (which dictates the penetration ability).

eBeam power The processing speed of the eBeam system (which translates into the volume of food that can be processed per unit time).

EFSA European Food Safety Authority.

Electron beam technology (eBeam technology) Ionizing radiation technology that utilizes commercial electricity to generate energetic electrons to create ionization events.

FD&C Food, Drug, and Cosmetic Act.

FDA Food and Drug Administration (US).

FSMA Food Safety Modernization Act.

FSSAI Food Safety and Standards Authority of India.

Gamma radiation Ionizing electromagnetic radiation. In the context of this chapter is the radioactive decay of the isotope cobalt-60 that generates a stream of energetic photons.

Gray (Gy) One joule of radiation energy absorbed per kilogram of matter.

HACCP Hazard Analysis and Critical Control Point.

HEEB High energy electron beam irradiation technology that utilizes electrons that have 10 MeV (million electron volts) energy.

IAEA International Atomic Energy Agency.

*Currently at SpaceX, Hawthorne, CA.

Ionizing radiation Electromagnetic (or other type of nuclear) radiation that has sufficient energy to cause ionization events in atoms it encounters.

IPPC International Plant Protection Convention.

LEEB Low energy electron beam irradiation technology utilizing electrons that have energy ranging below 1 MeV.

LEEX Low energy X-ray irradiation technology that utilizes low energy X-ray radiation below 300 keV (kilo electron volts).

Linac Linear accelerator, a type of eBeam generating equipment.

NNSA National Nuclear Security Administration (US).

Phytosanitary Treatment The treatment of imported agricultural products to eliminate agriculturally harmful insects and pests.

USDA-APHIS US Department of Agriculture-Animal and Plant Health Inspection Service.

WTO World Trade Association.

Introduction

Professor Norman Borlaug, winner of the 1970 Nobel Peace Prize once said, “You can’t build a peaceful world on empty stomachs and human misery.” This prophetic saying is extremely relevant today, if not more so than 5 decades ago. Despite dramatic improvements in global food supply chains since the 70s, over a billion people (~14% of the global population) still go to bed hungry every night. While food insecurity stems from a wide combination of social, political, and economic factors, technological limitations also drive food insecurity. Among the most significant of these technical factors are spoilage of food during transport, food waste resulting from improper storage, and food contamination with microbial pathogens. These factors combine to hinder efforts at food relief and result in a tragic situation where logistical realities prevent food from reaching places where it’s needed the most.

Few technologies in the food industry, except perhaps genetically modified crops, have received more scrutiny and been the subject of as much controversy as food irradiation. The British scientists Appleby and Banks were awarded their patent on food irradiation over 115 years ago, in 1905. Their invention was intended to bring about an improvement in the condition of foodstuffs and their general keeping quality. This technology, however, has moved beyond just improving the quality and safety of foods. It is now being commercially used for improved food packaging, improved seed germination concepts, and improved seedling emergence as well (Pillai and Shayanfar, 2015a, b; Hertwig et al., 2018; Beyaz et al., 2016).

The globalization of foods has brought along challenges related to the spread of microbial pathogens via foods, the potential spread of invasive insects and pests, and the potential for significant losses during transportation across continents. Microbial pathogens continue to be a major issue even in developed countries. In the United States for example, the Centers for Disease Control and Prevention estimate that as many as 48 million people get sick and about 3000 die each year from microbially contaminated foods. The situation in other parts of the world may be significantly more dire. However, in a majority of countries, disease surveillance is not as developed and, therefore, the exact magnitude of foodborne illnesses is never known. Ionizing radiation technology is a proven technology to reduce or eliminate foodborne pathogens. Food irradiation for food safety applications is in commercial use in over 40 countries, with China leading in the volume of food that is irradiated. In addition to the potential spread of the pathogens via foods, ionizing radiation is growing in popularity for use as a technology for the phytosanitary treatment of agricultural commodities.

Phytosanitary treatment refers to the technologies to eliminate the potential of spread of invasive insects and pests from one geographical region to another. The spread of such insects can have devastating consequences in prime agricultural regions of the importing countries. Currently a variety of technologies including chemical fumigation (with methyl bromide), cold treatment and elevated temperature treatments are used for a variety of agricultural products. However, with the growing demand for higher quality and chemical-free fresh and processed foods, these conventional techniques are being replaced by ionizing radiation technologies. Besides the application of ionizing radiation technology on the food directly, this technology is finding increasing number of applications that one can describe as “food industry-related applications.” These will include the use of the technology for improving the quality of plastics used in food packaging in terms of polymer characteristics as well as the environmental persistence of food packaging polymers.

Besides improving the quality of polymers, ionizing radiation technology has now replaced hydrogen peroxide as the chemical sterilant for sterilizing aseptic packaging materials. Thus, it is evident that ionizing radiation technology is impacting the food industry in a number of ways not generally realized.

Ionizing radiation technology, however, is a catch all term for primarily three different technologies; namely, cobalt-60 based gamma irradiation technology, accelerator-based electron beam (eBeam) technology, and X-ray technology. Therefore, it is critically important to understand the key differentiating characteristics of these three distinct technologies, but also appreciate the nuanced differences in order to understand the reason(s) why the popularity of gamma irradiation technology is waning compared to eBeam and X-ray technologies. This chapter attempts to provide the reader a detailed discussion of eBeam and X-ray technologies and how they are being commercially used around the world. The reasons for the slow eclipse of gamma irradiation as the go-to technology for the food industry is also presented as part of this chapter.

Challenges the food industry face requiring ionizing radiation technology

To understand the challenges the food industry faces in terms of quality and safety requires an appreciation of the world of microorganisms. Microorganisms have been on this planet for almost 3.8 billion years, whereas modern humans have been around for only approximately 200,000 years. During this period, microbes have had to endure extremely adverse conditions—especially during this planet's origins. Not only have microorganisms adapted themselves to extreme conditions (temperature, pressure, oxygen concentrations, pH, etc.) they have ended up colonizing all known environments on earth, including the bodies of all species, insects, plants, and humans. They also outnumber humans at levels that are unimaginable. For example, a gram of soil contains at least an order of magnitude more microbes than the entire human population! Therefore, when one looks at the production of food in the natural environment and the processing of food in human-engineered processing facilities, foods will invariably harbor microorganisms.

While many species of microbes are benign, certain species can cause undesirable effects on food. Yeasts and molds cause extensive spoilage of foods, and their removal can greatly increase shelf life and improve storage of both fresh and processed foods. Besides spoilage, there are pathogenic microorganisms such as *Salmonella* spp., toxigenic *E. coli*, and *Listeria monocytogenes* that are known to cause illnesses and death in humans. According to the US Centers for Disease Control & Prevention (CDC), approximately 1 in 6 Americans (~48 million) get sick from foodborne pathogens annually and approximately 3000 die each year from foodborne pathogens (Scallan et al., 2011). Most of the illnesses are caused by viruses (58%), followed by *Salmonella* spp. (11%), *Clostridium perfringens* (10%), and *Campylobacter* (9%). Therefore, the food industry must rely on technologies that eliminate or at least reduce the exposure of humans to these pathogens. Many of these pathogens in the environment arise from humans and farm animals through improper disposal of animal and human wastes. These pathogen-laden wastes reach food crops through irrigation water, contaminated soil, manure applications, and via contaminated farm workers. In terms of the meat industry, gastro-intestinal pathogens within these animals contaminate the meats prepared from these animals. This is particularly a major concern when meat products are prepared from the mixing and grinding of meats from different parts of the animals (e.g. ground beef). Eggs can get contaminated from *Salmonella* infected chickens. Poultry meat can get contaminated from *Salmonella* spp. or *Campylobacter* spp. that are often present within the intestinal tract of poultry.

The food industry has relied on the HACCP (Hazard Analysis and Critical Control Point) system to manage the microbiological, physical, and chemical safety of foods. In the US, the FDA has instituted the Food Safety Modernization Act (FSMA) in 2011 to establish preventative measures to control microbiological hazards. FSMA covers several different but related topics such as prevention, inspection and compliance, response, food imports, and building partnerships among critical stakeholders. Food producers, processors, and retailers around the world are challenged with providing high quality, microbiologically safe, and environmentally sustainable foods to consumers (Pillai and Shayanfar, 2015a, b). Fresh produce is particularly vulnerable to microbial pathogens since they are very often grown in open fields, are handled extensively, and because of their perishability cannot be treated by any heat-based pathogen control technologies. For example, berries such as strawberries, blueberries and blackberries can be contaminated at the pre-harvest stage via irrigation, fertilizers, soil, wildlife, and domestic animals. Additionally, berry-associated outbreaks due to cross-contamination have occurred at the post-harvest stage through field workers, food handlers, contact surface, packaging materials, and during processing. It is also now known that viruses that are transmitted through the fecal oral route can get internalized into leafy greens such as lettuce (DiCaprio et al., 2012).

Besides foodborne pathogens, food spoilage due to lack of appropriate storage facilities or poor transportation infrastructure has global ramifications. The reasons for this significant loss are primarily due to lack of food-chain infrastructure, poor storage capabilities, poor transportation logistics, and, unfortunately, lack of knowledge or adoption of storage technologies (Nellemann, 2009). In India, the lack of cold storage at both wholesale and retail outlets results in almost a 50% loss of fresh produce (Nellemann, 2009). In Southeast Asia, more than one third of the rice production is lost due to pests and spoilage (FAO, 2011). The loss of food in the food supply chain due to food waste is quite different in developing countries as compared to countries in the developed parts of the world. The majority (60%) of the food in the developed parts of the world is lost at the end of supply chains, for example in homes and at retail. This is in contrast to the majority (~75%) of the food being lost much earlier in the supply chain (i.e., on farm and during transport and processing) in the under developed parts of the world (Godfray et al., 2010). Therefore, the food industry must be strategic in deciding where appropriate technologies are implemented depending on the region of the world.

Thanks to the growing buying power of the populace around the world, there is an increasing need for a variety of fresh produce all 12 months of the year. Therefore, it is not surprising anymore for retailers to be offering tropical fruits in middle of winter to consumers in western Europe. Similarly, consumers in the tropics are now able to purchase apples, cherries, and peaches many months of the year. Additionally, due to the growing migration of people, ethnic dishes are becoming mainstream around the world. For example, the growing Hispanic population in the US, with their increasing buying power and the growing popularity of Mexican cuisines in the US, have resulted in significant increases in the import of fruits such as guavas, mangoes, and limes from Mexico into the US.

However, the USDA-Animal and Plant Health Inspection Service (USDA-APHIS) has strict requirements in terms of preventing the accidental introduction of insects and pests via these agricultural commodities. The USDA-APHIS legacy treatments have included fumigation using methyl bromide, hot water dips and cold temperate storage. However, the quality of the fruits deteriorates or is not maintained when such treatments are applied. The USDA-APHIS has spent a considerable amount of resources to explore the implementation of ionizing radiation technologies for phytosanitary applications. Phytosanitary regulations pertain to the transboundary shipment of agricultural commodities around the world. The International Plant Protection Convention

(IPPC) is a global agreement that focuses on preserving standardization of plant health practices around the world and was established to prevent the introduction of regulated pests and pathogens to help protect cultivated and wild plants in different regions of the world (Pillai et al., 2014).

Food security (lack of adequate food supplies) is also of strategic importance to countries globally. The COVID-19 pandemic has heightened our awareness of the need to consider technologies to address food security as well. This pandemic has caused the closure of several meat and cheese processing plants across the USA. In April 2020, based on a survey of 115 meat and poultry processing facilities in 19 states, the CDC reported that there were approximately 5000 cases of COVID-19 and 20 deaths in food processing facilities (Dyal et al., 2020). By April 2020, almost 25% of the US' meat packing plants were closed down due to the rapid spread within these food processing facilities. In April 2020, Tyson, Inc. closed a meat processing plant in Iowa after hundreds of employees were infected. The situation is so dire that the chief executives of several leading food companies have alerted to the possibility of the US food supply chain breaking (Arkin, 2020).

So, ionizing radiation technology has a key role to play in preventing food spoilage, thwarting food security challenges, eliminating foodborne pathogens as well as controlling the accidental introduction of insects and pests. It must be noted, however, that the technology has to be customized to the specific application so that the technology is not only able to meet its intended application, but it is economically viable and sustainable. The conventional idea that the technology will be introduced and implemented by governmental agencies is flawed at the present time. One must consider the private sector to be able to finance and maintain the technology for the different food industry applications.

Ionizing radiation technologies in the food industry

As noted earlier, the use of ionizing radiation technology is not new. British scientists patented this technology for the preservation of foods in 1905. By 1921, scientists with the United States Department of Agriculture were recommending its use to control the protozoan pathogen trichinae in pork. Food irradiation is one of the mostly extensively studied food processing technologies, but, unfortunately, the least understood and often impugned technology ever (Pillai, 2016). In 1958, the US Food and Drug Administration amended the Food, Drug and Cosmetic Act (FD&C) to designate food irradiation as a food additive and not as a food processing technology (FDA, 2018). This was a pivotal regulatory decision because designation of this technology as a food additive requires that all foods (human and pet food) in the US that are treated with ionizing radiation be specifically labeled as such. Some in the food industry blame the labeling requirement as the key reason why the technology is not more widely adopted by the industry. However, on careful analysis it is evident that the reasons for the lack of widespread adoption are multi-fold. These include the lack of processing facilities dedicated for food processing, the capital and operational expense associated with this technology, as well as the general lack of deep actionable information about this technology among many of the decision makers in the food industry. Currently, gamma irradiation using cobalt-60, electron beam and X-ray irradiation using accelerator technologies are the main technologies used in the food industry. Gamma irradiation using cobalt-60 has historically been the mainstay of the irradiation technology in the food industry.

Underlying principles of how ionizing radiation technology controls microbial populations

Ionizing radiation, whether it is produced by cobalt-60, electron beam or X-ray technology, inactivates microbial cells by causing a number of irreparable double stranded DNA and RNA breaks in the microbial cells that are in the way of the electrons or photons. When photons from cobalt-60 encounter electrons within the orbital shells of atoms in the food materials, these electrons are ejected from their orbital shells (causing ionization events, hence ionizing radiation). These ejected electrons pick up some of the energy from these collisions and they themselves cause ionization events in adjoining atoms. Thus, each electron ends up creating a cascade of ionization events until the ejected electrons lose their energy to cause any further ionization events. Ionizing radiation does not discriminate between a pathogen or a non-pathogen or whether they cause damage to a DNA molecule or an RNA molecule, or a protein or a carbohydrate. The targets of ionizing radiation depend on the molecular weight. Since DNA is the largest molecule within microbial cells, compared to proteins or carbohydrates, at a given dose, most of the damage occurs in DNA molecules rather than in proteins. The electrons can cause direct effect on DNA molecules by the ionization events described above.

Additionally, the electrons will cause radiolysis of water molecules, which result in the release of highly reactive but short-lived free radicals such as hydrated proton, hydroxyl radicals, hydrogen gas, hydrogen peroxide, as well as aqueous electrons. The effects of hydrolysis depend on the amount of energy absorbed per unit mass of material (i.e., absorbed dose, measured in Grays/kilograys and denoted as Gy or kGy). The DNA is the largest biomolecule in the cell and, therefore, it is the most ionizing radiation sensitive molecule in cells. The microbial cell can repair single and double stranded breaks in its DNA. However, if the double strand breaks are juxtaposed across each other in different strands of the DNA, the microbial cells are incapable of repairing this type of damage. It is estimated that with each 1 kGy of ionizing radiation exposure, as many as between 10–100 double strand breaks occur. It is precisely for this reason that when food is treated with ionizing radiation, the decline in the bacterial bioburden results in extended shelf-life. Double strand breaks are the most lethal form of DNA damage because they halt DNA replication. With increasing dose,

ionizing radiation can also affect plasmid DNA, RNA molecules, cellular membranes, and even structural and functional proteins (e.g., enzymes).

Structural proteins, catalytic proteins (enzymes), and most vitamins are not damaged at doses regularly used in food irradiation (Smith and Pillai, 2004). Exposure to very high doses can, however, cause damage to macro molecules, such as proteins. The reason that maturation is retarded or inhibited is because the genes of many of these enzymes may have been structurally damaged during the double strand and single strand breaks. Previous studies have shown that for a dose of 100 Grays (0.1 kGy), 2.8% of the DNA, 0.14% of enzymes, and 0.004% of amino acids will be damaged (Pillai and Shayanfar, 2017). Therefore, the microbial DNA is damaged by both direct effects of the energetic electrons or from the highly reactive free radicals produced by the radiolysis of water molecules. Bacterial cells will try to repair the damage that has occurred during ionizing radiation. The cells attempt to repair their DNA damage using a variety of specific and non-specific repair mechanisms such as methyl directed mismatch repair, guanine oxidations, nucleotide excisions, base excisions, recombination repairs as well as the generic SOS repair systems.

Microbial inactivation in response to ionizing radiation is calibrated in terms of D-10 values. The D-10 value of an organism is the ionizing dose (measured in kGy) required to achieve a 90% reduction in its population. There is a linear relationship between the increasing doses and microbial inactivation. Factors controlling radiation resistance include the general physiological differences between the microbial cells (for example the D-10 value of *E. coli* is 0.1 kGy, while the D-10 value of *Salmonella* spp. is 0.2 kGy), the physical state of the food (fresh/refrigerated as compared to frozen), the type of food (fresh produce vs ground beef vs poultry), presence/absence of oxygen, and the atmosphere within the food package, as well as the physiological state of the pathogen (example if the cells had been exposed to acid stress or nutritional stress, etc.) (Clemmons et al., 2015). Table 1 is an illustrative example of how the D-10 values of organisms could vary, depending on the product temperature, organism type, and packaging conditions.

Historically, the food industry always targets a 5-log reduction of target pathogens in commodities such as spices and ground beef. However, with improved Good Agricultural Practices at the farm and improved food processing technologies within processing plants (associated with HACCP), the probability of large numbers of microbial pathogens on foods is very small. Therefore, the rationale for choosing a dose to target 5-log reduction is debatable. However, internationally recognized standards such as ISO 14470:2011 can guide the choice of an appropriate dose as well as requirements for the development, validation, and process controls for food irradiation.

It must be noted that the choice of the appropriate irradiation dose for food irradiation applications depends on the deep understanding of the expected pathogen bioburden as well as not employing doses that could cause sensory changes in the foods. It is for this reason that careful attention is paid to use this technology at the lowest possible dose. This implies that only foods with superior microbiological quality is processed with this powerful technology. Therefore, ionizing radiation technology should only be used to increase the value of a food by assuring microbiological safety rather than employing this technology to reclaim heavily contaminated foods. It is important that this concept be effectively communicated to those interested in adopting this technology.

Ionizing radiation technology related terminologies of relevance in the food industry

The penetrating power of ionizing radiation is a function of their energy (measured in electron volts or million electron volts) (keV or MeV). Energy dictates the penetration capability of the ionizing radiation. Cobalt-60 has gamma energies between 1.17 and 1.33 MeV. They are photons and, therefore, have no mass and no charge. Therefore, their penetration ability is very high. In addition to the ionizing radiation energy, another key parameter associated with food irradiation technology is “dose”. Dose is defined as the absorbed energy, which is measured in grays designated as Gy. 1 Gray is the deposition of 1 joule of energy per kg of matter. Dose determines the treatment parameter and it determines the specific application the technology is used for. In food irradiation, doses in the 1000 of Gy's are utilized. For example, the maximum dose that the FDA has approved for fresh produce in the US is 1000

Table 1 D-10 values of different microbial targets as a function of product type, product temperature, atmospheric conditions within package.

Product type	Product temperature (°C)	Pathogen	D-10 value (Gy)
Ground beef patties	5	<i>E. coli</i> 0157:H7	0.27–0.38
Ground beef patties	– 15	<i>E. coli</i> 0157:H7	0.32–0.63
Ground beef	3	<i>Salmonella enteritidis</i>	0.55–0.78
Beef	5	<i>E. coli</i> 0157:H7	0.30
Ground beef	5	<i>Campylobacter jejuni</i>	0.16
Deboned meat	5	<i>B. cereus</i> spores	2.56
Beef	5	<i>L. monocytogenes</i>	0.45
Poultry (air packed)	0	<i>Salmonella heidelberg</i>	0.24
Poultry (vacuum packed)	0	<i>Salmonella heidelberg</i>	0.39

Grays (1 kGy). Dose rate (measured in Gy/s) is the rate at which the energy is deposited in the target material. Dose rate, therefore, will translate into the processing line speeds when these technologies are employed.

The dose rate of gamma irradiation is significantly lower than commercial scale X-ray or eBeam irradiation processes (Miller, 2005). Many of the commercial eBeam facilities have dose rates in the range of 3000 Gy/s (3 kGy/s). Electron beam and X-ray equipment have an additional parameter, termed power, measured in kilowatts (kW). Beam power determines the processing speed of the equipment. The higher the beam power, the higher the product throughput (Brown, 2015). Therefore, when deciding on the appropriate eBeam and X-ray equipment, one has to have a clear understanding of the target doses for the specific application (kGy) as well as the energy (MeV), and the power (kW).

Current challenges associated with gamma irradiation in the food industry

Gamma radiation is used in about 40 countries around the world. The gamma radiation source (cobalt-60) is stored within a deep pool of water. The gamma source is placed under water when not in use because the source cannot be switched off.

The food in pallets are conveyed into the irradiation chamber using automated conveyor and product handling systems. Since photons have very good penetrating abilities, the primary advantage of the gamma irradiation process is that the pallets can be treated without the need to “break-down” the pallet into single cases (as in the case for electron beam facilities). For the actual irradiation process, the cobalt-60 source is raised out of the water and the pallets of food are automatically brought into the irradiation chamber and placed around the cobalt-60 radioactive isotope “pencils” at defined locations for defined periods and position so that they receive the minimum required dose, and ensure that the product receives as uniform a dose as possible. Since the gamma source cannot be switched off, there are obvious challenges associated with possible occupational exposure, radioactive source theft, storage of spent sources, and disposal of spent sources. These challenges have become more acute—especially due to the potential dangers posed by terrorism. Cobalt-60 isotope-based gamma sources have a 12% loss in specific activity each year due to radioactive decay. Gamma sources are priced on a per curie basis. Curie is 3.7×10^{10} disintegrations per second. Curie is, however, not an SI unit. The SI unit for ionizing radiation is the Becquerel.

The cost of gamma sources has increased substantially over the past decade, especially since there are only a couple of cobalt-60 suppliers around the world and because of the cost associated with the production of cobalt-60 gamma sources. The purchase of the cobalt-60 sources will invariably also include the cost of return for recycling as well as additional costs associated with the regulatory burden associated with radioactive materials. More so, smaller gamma irradiation facilities must pay substantially more compared to the large multinational gamma irradiation service providers. Current estimates for 1 curie of cobalt-60 is around \$5.00 (personal communication). A majority of the food irradiation facilities around the world require between 0.5 and 1 million curies of Cobalt-60. Therefore, the cobalt-60 cost alone (excluding shipping, installation, recycling/disposal) will be around \$2.5 million and \$5 million. In addition to these monetary costs, the legal, environmental, and security costs associated with maintaining and operating a cobalt-60 facility can be steep. There are anecdotal comments that suggest the security costs associated with a gamma facility is actually higher than the cost of cobalt-60. Because of the myriad of security challenges, the International Atomic Energy Agency (IAEA) and the US National Nuclear Security Administration (NNSA) are keen on replacing these high activity radioactive sources out of the commercial application arena (NNSA, <https://www.energy.gov/nnsa/office-radiological-security-ors>).

Basic principles of electron beam technology

There are several excellent books and book chapters discussing eBeam technology and how the technology can be integrated into food processing (Miller, 2005; Clemmons et al., 2015; Pillai and Shayanfar, 2015a, b; Shayanfar and Pillai, 2015; Brown, 2015).

The primary differentiation between cobalt-60 based gamma irradiation and electron beam (eBeam) technology is that eBeam technology does not involve radioactive isotopes. Electrons are generated using a cathode (electron gun) in a vacuum environment using commercial electricity. The electrons are accelerated to 99.99% of the speed of light at which time they have acquired energy of about 10 MeV. These 10 MeV electrons then exit the accelerator. After this beam of electrons exits the accelerator, it enters the scan horn. Within the scan horn, the electrons are oriented, focused and scanned in a sweeping pattern allowing the electrons to be “scanned” across the cases of food in a very defined and controlled manner.

There are basically three fundamental designs of electron beam equipment that could potentially be used in food irradiation; namely, pulsed machines (linear accelerators or linac), Continuous Wave (CW) machines (e.g., Rhodotron) and Direct Current (DC) machines (e.g., Dynamitron). Linacs is the generic term for accelerators that produce a high energy, high intensity burst of radiation. The bursts of radiation are the “pulses.” In the Rhodotron, the electron beam is not pulsed but composed of high intensity “bunches” that occur at very high repetition rate. In the Dynamitron-class machines, the electrons are neither pulsed nor in bunches. Instead, there is a constant stream of equally intense electrons. Table 2 below highlights some of the differences between linac, Dynamitron, and Rhodotron-class accelerators.

For most food irradiation applications, high doses and high throughputs are desired. Therefore, linacs and Rhodotrons are the ones that are finding increasing applications in food processing. Fig. 1 is a schematic and photo illustration of a linac-style accelerator. Electron beam accelerators are also used for sterilization processes in the medical industry (Kalia, 2021).

Table 2 Differentiating characteristics of the DC, CW, and pulsed type accelerators.

Parameter	DC accelerator	CW accelerator	Pulsed accelerator
Genre	Dynamitron-style	Rhodotron-style	LINAC style
Maximum energy used commercially	5 MeV	7.5–10 MeV	10 MeV
Power (commercial line speeds possible)	High power; as high as 100 kW	High power; as high as 800 kW	Limited; maximum around 20 kW
Electrical use efficiency	High	Medium	Low
Physical size	Large	Medium	Small

The photos are from a commercial scale panoramic food irradiation facility. Courtesy: Texas A&M University-National Center for Electron Beam Research.

The maximum electron energy that can be used for commercial food processing is 10 MeV. The penetration ability of 10 MeV electrons is significantly less than that of the cobalt-60 based gamma irradiation. In gamma irradiation, entire pallets of products can be treated at a time. However, in eBeam processing, the pallets have to be “broken-down” into individual cases and they need to be conveyed through the eBeam system (Fig. 2). In commercial eBeam food processing, the key parameter that needs to be considered is the maximum thickness of material that the beam can penetrate through. The areal density (g/cm^2) or mass of material in a certain area is the most common definition of “thickness” in food processing.

$$\text{Areal Density} = \frac{\text{boxweight}(\text{lbs}) \times 70.4}{\text{length of box} \times \text{width of box}} = \text{g}/\text{cm}^2.$$

A 10 MeV eBeam accelerator can penetrate up to $3.3 \text{ g}/\text{cm}^2$ using a single sided treatment or up to $8.3 \text{ g}/\text{cm}^2$ using a double-sided treatment. Double sided treatment refers to the product being treated with 10 MeV eBeam from top and bottom or the product is flipped over and treated from the other side. If the case of food has an areal density that is greater than $8.3 \text{ g}/\text{cm}^2$, it cannot be processed with eBeam (since the beam will not penetrate the product). In this situation one has the option to repackage the product so

Fig. 2 Schematic of how X-rays are generated from an eBeam linac.

that the areal density falls between 3.3 and 8.3 g/cm² or, if this is not possible, then X-rays have to be used; if this is not possible, gamma irradiation is the only choice.

Worldwide, the maximum energy for eBeam technology that can be used for food irradiation is 10 MeV. The reason for this upper limit on energy is that higher energies could potentially induce transient radioactivity in highly dense materials such as bones, etc. The international harmonization entity, Codex Alimentarius regulates the use of irradiation technology for transboundary shipment of foods. This multinational body has also established 10 MeV energy (similar to the US) as maximum eBeam energy for food irradiation.

Basic principles of X-ray technology

A major drawback of eBeam based food processing is the requirement that the cases must fit within the areal density specifications and that pallets cannot be treated as such. Other than gamma irradiation, X-ray technology is the only other choice to process entire pallets. Miller (2005) is an excellent resource for details about the X-ray technology and the engineering principles of X-ray based food processing. Briefly put, X-ray generation from eBeam in a linac or Rhodotron is based on placing a very high atomic mass material such as tantalum or gold directly in the path of a stream of high energy (5 MeV or 7.5 MeV) eBeam. The collision of high energy electrons results in the formation of X-ray photons. X-ray photons are like gamma irradiation in that they have very high penetration capabilities (compared to eBeam). However, the energy of X-ray (either 5 MeV or 7.5 MeV) is significantly greater than the energy of cobalt-60 based gamma irradiation. Also, X-ray photon beams can have a much higher dose rate compared to gamma photon beams: ~ 100 Gy/s as compared with ~100Gy/min) (Hieke, 2015).

Fig. 2 is a highly simplified schematic of how X-rays are generated from a linac accelerator. In the US, eBeam energies as high as 7.5 MeV can be used to generate X-rays for food irradiation. However, worldwide, the maximum energy for X-ray is still set at 5 MeV. The major advantage of X-ray based food processing is that entire pallet can be treated at a time. Moreover, since the dose rate is significantly lower than that of eBeam processing, X-ray technology is ideally suited for low dose food processing applications such as phytosanitary treatment as well as for extending the shelf-life of fresh produce. However, the conversion of 7.5 MeV electrons into X-rays in X-ray processing is quite inefficient (~ 12.5%). Therefore, the cost of X-ray processing will be more than eBeam processing. The rule of thumb is that eBeam processing will be cheaper than X-ray processing. However, there are several other factors that can influence the overall cost of eBeam processing (discussed below).

Low energy electron beam processing technology

One of the major shortcomings of the high energy (10 MeV) eBeam technology platform is the capital expense (a turnkey system excluding building and land is approximately \$6–9 million). These high energy eBeam (HEEB) systems are also hampered by the need to have specialized concrete shielding to contain the ionizing radiation while the system is in operation. In general, the high capital investment has precluded the adoption of HEEB technology by most food processors. Around the world, the model for food irradiation currently involves transporting the food by truck to a commercial irradiation service provider. However, given the cost of transportation, turn-around time, and vulnerability to steep price increases, many of the major users of the technology in the food industry, such as spice and ingredient processors, are interested in bringing eBeam technology into their facilities as either in-line or end of line eBeam irradiation systems. Low energy eBeam (LEEB) technology offers this opportunity to be brought into commercial operations as either in-line systems or end of line sterilization/decontamination systems. Low energy eBeam systems can be broadly defined as generating electrons having energies ranging between 80 and 1000 keV. Since the electron energy in currently available commercial LEEB ranges between 180 and 300 keV, these are self-shielded units. However, as expected, LEEB can only be used for surface sterilization.

Within the food industry, the early adopters of LEEB have been the aseptic packaging and the printing ink industries. Low energy eBeam (LEEB) systems (~ 180 and 300 keV) are now commercially available for these industries (Pillai and Shayanfar, 2015b). The LEEB technology platforms are now offered as part of the original equipment by aseptic packaging equipment manufacturers such as TetraPak as part of their Tetra Pak® E3/Speed, E3/flex, and E3/CompactFlex platforms (<https://www.tetrapak.com/tetra-pak-e3->

Table 3 D-10 Values of Bacillus spores when exposed to 100 keV electrons and 10 MeV electrons.

Bacillus sp.	D-10 value	
	100 keV	10 MeV
<i>B. pumilus</i>	1.34 kGy	2.12 kGy
<i>B. megaterium</i>	3.46 kGy	4.11 kGy
<i>B. subtilis</i>	1.01 kGy	2.05 kGy

ebeam). According to the company's commercial marketing claims, the new eBeam based sterilization systems offer advantages such as higher production capacity without any increase in equipment footprint and up to 20% cost savings due to improved efficiency. A key advantage of LEEB for aseptic packaging as compared to the legacy hydrogen peroxide-based sterilization is the complete avoidance of using chemicals on packaging materials in direct contact with food and the ability to sterilize packaging without leaving any chemical residues. The electron energy in LEEB is approximately 200 keV. Low energy eBeam systems are characterized by very high dose rates compared to HEEB due to their short ranges. Previous studies in our laboratory have shown that higher dose rates could achieve greater microbial killing (Urgiles et al., 2007) (Table 3). The response of microorganisms in terms of their inactivation kinetics and their molecular responses (genomic and metabolomic) at varying dose rates needs detailed investigations (Bhatia and Pillai, 2019).

The LEEB platforms are gaining traction as in-line sterilization solutions within the single use device (e.g., syringe) manufacturers, by the pharmaceutical industry such as in vial filling, and lyophilization processes. Fig. 3 shows the self-shielded LEEB system (energy between 180 and 200 keV) for continuous syringe tub decontamination. Fig. 4 depicts how multiple LEEB systems, when configured appropriately, can be used to achieve complete in-line sterilization of a tub of syringes within the manufacturing space of a single use device manufacturer.

Besides the use in aseptic packaging and in the single use device manufacturing, commercial LEEB is now available for the surface sterilization of spices such as black pepper, cumin, aniseed, etc. Buhler, Inc., the Switzerland-based original equipment manufacturer of food industry equipment is now marketing Laatu™, a LEEB platform for the spice and ingredient industry (Fig. 5). The company's marketing literature states that 5-log reduction of microbial pathogens can be achieved with the Laatu™ LEEB platform. This, once again, is a self-shielded microbial reduction solution for industrial dry food processing. In this system, the spices/dry foods fall via gravity through an electron cloud generated from two low energy (≤ 300 keV) eBeam "lamps" (Fig. 6). The reported throughput is approximately 1 ton/h delivering a minimum dose to achieve a 5-log reduction of *Salmonella* spp. on spices and dry foods.

International regulations governing ionizing radiation technology in the food industry

United States

In the US, the use of ionizing radiation technology in food processing is governed by the FDA, USDA-FSIS and the USDA-APHIS. The FDA controls the labeling requirements and the approvals for food applications. The USDA-APHIS controls the minimum doses that can be used for phytosanitary applications. The USDA-FSIS regulates the use of the technology in the meat and poultry industries. Historically, food irradiation in the US is governed by the 1958 Food Additives Amendment of the Food Drug and Cosmetic (FD&C) Act as a "food additive". Per this Act, food additives must be specifically labeled with the radura symbol and must state the phrase, "treated with radiation" or "treated by irradiation." Thus, all irradiated foods that are sold at retail must have this labeling at the point of sale. The FDA also has specific stipulations as to the type of packaging materials that can be used, the maximum dose that these materials can receive, etc. Presently, in the US, the following foods (Table 2) are permitted to be treated with ionizing radiation (either gamma, eBeam or X-ray). The foods include fresh fruits and vegetables, meat (from cattle, sheep, swine and goat), poultry, shell eggs, iceberg lettuce and fresh spinach, spices, seeds for sprouting and molluscan shellfish. Table 4 shows the dose limits and the foods that can be treated with ionizing radiation in the US.

Per the FDA regulations, one cannot use the technology on fresh produce and make a claim that pathogens are eliminated (because the regulation is specifically approved for only the use of this technology for growth/maturation inhibition). Only iceberg lettuce and spinach are currently permitted for use for "pathogen elimination" by this technology. In the US, ionizing radiation is permitted for treating animal diets (bagged complete diets, packaged feeds, feed ingredients, bulk feeds, animal treats and chews). However, the dose cannot exceed 50 kGy. For complete poultry diets and poultry feed ingredients, the dose cannot be below 2 kGy and cannot exceed 25 kGy. The upper dose limit is based on the assumption that the irradiation treatment is being used to control *Salmonella* spp. Importantly, if an irradiated feed ingredient is less than 5% of the final product, the final product can also be irradiated without being considered re-irradiated.

Fig. 4 Schematic of how 3 LEEB emitters (magnified in the upper circle) are configured to achieve the sterilization of the syringe tub (courtesy SKAN US, Inc. Raleigh, NC).

European Union

Interestingly, the European Union is more supportive of food irradiation than genetically modified foods. Contrary to popular belief, food irradiation is legal in the European Union per Articles 7(3) and 3(2) of Directives 1999/2/EC of the European Parliament. Food irradiation does occur in the EU, albeit, at significantly lower volumes than in other countries such as the US, China, and India. The irradiation of dried aromatic herbs, spices and vegetable seasonings is authorized across the EU by Directive 1999/3/EC. There is a community list of food and food ingredients that can be treated with ionizing irradiation. In addition to this “community

Table 4 List of foods and food items permitted for ionizing radiation treatment in the United States (FDA, 2019).

<i>Food/food-related item</i>	<i>Specific application</i>	<i>Maximum allowable dose (kGy)</i>
Fresh, non-heated processed pork	Pathogen control	0.3–1.0
Fresh/frozen uncooked poultry products	Pathogen control	3
Refrigerated, uncooked meat products (sheep, cattle, swine and goat)	Pathogen control	4.5
Frozen uncooked meat products (sheep, cattle, swine and goat)	Pathogen control	7
Fresh/frozen molluscan shellfish	Pathogen control	5.5
Fresh shell eggs	Pathogen control	3.0
Dry or dehydrated spices and food seasonings	Microbial disinfection	30
Fresh produce	Growth and maturation inhibition	1
Fresh produce	Insect disinfection	1
Fresh iceberg lettuce and fresh spinach	Pathogen control	4.0
Seeds for sprouting	Pathogen control	8.0
Dry/Dehydrated spices and food seasonings	Microbial disinfection	30
Dry/dehydrated enzyme preparations	Microbial disinfection	10
Wheat flour	Mold control	0.5
White potatoes	Inhibit sprouting	0.15

list of foods and food ingredients”, seven-member states have their own list of foods and food ingredients that are above and beyond the community list (European Union, 2019a, b). Unlike the US, the EU’s has much stricter rules governing the labeling of irradiated foods. In the EU, any irradiated foodstuff containing one or more irradiated food ingredients must be labeled with the words “irradiated” or “treated with ionizing radiation.” Therefore, if an irradiated product is used as an ingredient (e.g., spices on a pizza) the notation that the ingredient was irradiated should be mentioned in the list of ingredients. Presently, Belgium, Bulgaria, Czech Republic, Germany, Estonia, France, Spain, Hungary, Netherlands, Poland, and Romania treat one of more foods or food ingredients by ionizing radiation. Table 5 is a listing of the countries and the food items that are being commercially irradiated in the European Union and Table 6 is the irradiation doses that are used in the EU countries.

The European Food Safety Authority (EFSA) in 2011 recommended that irradiation should be considered as one of the several approaches to reducing pathogens in food and this technology should be integrated into a multi-hurdle strategy, thereby assuring public health protection (EFSA, 2011a). The EFSA panel also confirmed the toxicology and chemical safety of irradiated foods (EFSA, 2011b). Importantly, they also recommended that food irradiation should be based on risk assessment and on the desired risk reduction rather than on predetermined food classes, commodities and doses. They also recommended that upper dose limits should not be specified, but rather based on undesirable sensory chemical changes that may happen at increasing doses. The EU is presently receiving public comments regarding to expanding the approvals of the technology across a wider array of foods and also possibly changing the stringent labeling requirements.

China

China irradiates the largest volume of food. By volume, the irradiated chicken feet sold as a snack in convenience stores in China is among the largest commodity that is treated by ionizing radiation anywhere in the world. There is a paucity of reliable datasets about the actual volume of food that is irradiated in China. The last report was based on 2005 datasets. Based on these values, a total of approximately 150,000 tons of food was being commercially irradiated in China in 2005 (Kume et al., 2009). Based on information presented at conferences, etc., it is thought that over 250,000 tons of food is irradiated in China. There are six mandatory national standards in terms of the foods that can be irradiated in China; namely, the maximum dose, the packaging, and the labeling requirements. The different food classes are (1) fruits and vegetables, (2) beans and grains, (3) poultry (fresh/chilled/frozen) and meats, (4) cooked meats, (5) spices and dehydrated vegetables, and (6) dried fruits and nuts. China’s approved list of packaging materials closely resemble that of US and Britain. The maximum dose for cardboard is set at 10 kGy, while for Polyethylene-polyvinyl acetate co-extruded film the maximum is 30 kGy. Nylon 11 (nylon is a part of some food packaging polymers) has a maximum dose limit of 10 kGy, while Nylon 6 has a maximum dose limit of 60 kGy (FDA, 2019).

India

In India, the regulations governing commercial food irradiation are governed by the Food Safety and Standards Authority of India (FSSAI). In November 2015, this agency proposed a revised set of standards for foods and allied materials. In January 2016, India notified the World Trade Organization (WTO) about the revised food irradiation standards. The Indian food irradiation regulations categorize foods and associated materials in different classes (Tables 7 and 8). The food irradiation regulations in India are prescriptive and provide significant commercial opportunities to expand the technology for foods. For example, the technology is approved for Class # 8 foods (ethnic foods, military rations, space foods, ready-to-eat, ready-to-cook and minimally processed foods). There is significant flexibility in terms of the doses that can be used and the ability to use the technology for fully cooked foods. The ability to use this technology for cooked foods opens significant opportunities for widespread commercial adoption, for example, in foods prepared for long-distance trains, airlines, buses, etc. The ability to use the technology for creating emergency stockpiles for natural

and/or man-made disasters is another opportunity for commercial expansion of this technology. The specific mention of the min and max doses is empowering to commercial adoption. The irradiated foods have to be labeled with the radura logo in green color with information about the product identity, purpose of radiation processing, radiation processing facility and date of processing.

Future outlook

Choice of food irradiation technology- gamma or eBeam or X-ray?

Based on US and international trends, there is no doubt that gamma irradiation based on cobalt-60 or cesium-137 isotope-based irradiation technologies are on the way out of commercial use. The economics coupled with regulatory, environmental, and security challenges are factors against gamma irradiation. This brings up the question of the future of machine sources such as eBeam and X-ray technologies. Notwithstanding the challenges associated with the relatively small number of reliable suppliers of these technologies, the adoption of either of these technologies for food irradiation purposes has to be based on deep analysis that spans regulations, food industry adoption, decisions of who pays for the service, guaranteed volumes, capital costs, operating costs, as well as the location of the eBeam or X-ray food processing facilities. Further, the decision of adopting the appropriate technology

Table 8 Indian regulations governing dose limits for ionizing radiation processing of food-related allied products.

Allied Product	Application	Dose Limits (kGy)	
		Minimum	Maximum
Packaging materials for food and allied products	Bioburden reduction	5.0	10.0
	Sterilization	10.0	25.0
Food additives	Bioburden reduction	5.0	10.0
	Insect disinfestation	0.25	1.0
	Sterilization	10.0	25.0
Health foods, dietary supplements and nutraceuticals	Bioburden reduction	5.0	10.0
	Insect disinfestation	5.0	1.0
	Sterilization	10.0	25.0

**Fig. 7** Photo showing boxes of mangoes on the conveyor system being readied for eBeam processing. The mangoes arrive at the facility as pallets of mango boxes (shown on side).

depends on deep analysis of the engineering specifications and processing throughputs of the different technology platforms, costs (capital and operating).

The USDA-APHIS allows the technology to be used “in-country,” before the commodities are exported or “on arrival” in the US, subject to the commodity meeting strict quarantine packaging, transportation, and handling requirements. The eBeam facility of the National Center for Electron Beam Research at Texas A&M University is only one of 3 irradiation facilities that is approved by the USDA-APHIS for the phytosanitary treatment of regulated commodities on arrival in the U.S. This facility, in cooperation with the world’s largest retailer (Walmart, Inc.), treated millions of pounds of high value Mexican mangoes over 3 years using eBeam technology. The dose that was used was above 200 Gy and below 1 kGy (Fig. 7).

All of the market studies showed that the eBeam treatment was a superior treatment as compared to the legacy treatment of hot water for Mexican mangoes. The flavor profile of eBeam treated mangoes was better and the fruits could remain on the trees longer (since eBeam is gentler on the fruit compared to hot water). However, compared to hot water treatment, eBeam processing was costlier because of (a) the specialized transportation requirements, (b) paperwork to meet Mexican and US border personnel, and (c) eBeam processing costs. The mangoes were shipped to the facility as pallets. Since eBeam cannot treat entire pallets, the pallets had to be “broken down” and the single boxes had to be placed within carriers on the conveyor system for eBeam dosing (Fig. 7). There are significant labor costs associated with “breaking down” the pallet and for “re-building the pallets” for transport out of the facility after eBeam processing. These costs have to be reduced, to make the costs comparable to the current hot water treatment, to convince large retailers for wide scale technology adoption.

Based on an in-depth analysis of factors such as capital and operating costs, technology specifications (throughput, pallet level treatment, automation) it is clear that while eBeam processing of foods offers substantial benefits over status quo methodologies, the current design of eBeam facilities (built primarily for conventional meat pasteurization or medical device sterilization) are not suitable for phytosanitary treatment. With the construction of purpose-built facilities, eBeam phytosanitary treatment costs can be made comparable to or substantially lower than costs for hot water treatment. Table 9 below shows projected per-pound processing costs for low-dose phytosanitary treatment facilities.

Table 9 Projected annual eBeam throughput and costs (fixed and variable) for purpose-built phytosanitary treatment facilities.

<i>eBeam power (kW)</i>	<i>Calculated throughput</i>	<i>Variable costs</i>	<i>Fixed costs</i>	<i>Per pound processing costs (cents/lb)</i>
5	31,680 tons	\$485,000	\$2.34 million	4.55
20	126,720 tons	\$1.94 million	\$2.70 million	1.82
40	254,440 tons	\$4.84 million	\$2.94 million	1.36

Table 10 eBeam facility parameters by configuration.

<i>Parameter</i>	<i>5 kW</i>	<i>20 kW</i>	<i>40 kW</i>
Facility Cost	\$ 6.3 million	\$ 7.7 million	\$8.4 million
Annual amortized cost	\$ 1.6 million	\$ 1.9 million	\$ 2.1 million
Background power usage	4 kW	16 kW	32 kW
Hourly staff numbers	20	80	200
Annual production hours	2000	2000	2000

While facility fixed costs remain low even for high-powered facilities, variable costs (due to labor) rapidly eclipse the cost of equipment and electricity. These high labor costs are due to eBeam's primary limitation: the requirement for pallets of product to be broken down into individual boxes for processing due to the low penetrative power of eBeam phytosanitation. As facility throughput increases, tremendous work forces are required simply to de-palletize and re-palletize product. This work is physically demanding and must be maintained virtually non-stop to ensure that product continues to flow at a high rate through the electron beam. A breakdown of facility costs is included below (Table 10).

So, as facility size increases, facility staff requirements grow linearly with throughput, except for very large facilities where additional support staff and floor managers are required. While facility throughput can theoretically grow in linear proportion to beam power, this linear growth requires systemic changes to the design of a typical electron beam facility. Current electron beam facilities are designed with a single conveyor system for products. This conveyor then passes through the electron beam, and products receive a dose of irradiation. While this configuration is well-suited to applications where the power of the electron beam itself limits product throughput, the single-conveyor design imposes substantial throughput restrictions on products that require only a low dose of irradiation.

For example, in the National Center for Electron Beam Research at Texas A&M University, the 17 kW accelerator could theoretically process nearly 45,360 Kg (100,000 lbs.) of mango per hour. However, due to limitations on conveyor speed, this processing rate is reduced by almost 83% due to the inability of the conveyor system to "keep pace" with the maximum output of the electron beam accelerator. To rectify this problem, multiple (many) parallel conveyor systems are required. Instead of using a single conveyor, even the smallest of facilities (such as the 5 kW facility) would require four or more conveyors passing through a wide-aperture electron beam to take full advantage of the power output potential of the electron beam. In addition to changes to the conveyor system, reductions in the amount of labor required to de-palletize and re-palletize products would drastically improve per-pound processing costs.

Alleviating labor costs with mechanized or automated processes could result in even more significant cost savings. In our analysis, eBeam processing has the potential to significantly disrupt current industry norms for mango phytosanitation. However, it faces significant challenges to implementation as a result of the design of typical electron beam facilities that are not optimized for low-dose product processing at scale. To cost-effectively process mango, two major modifications are needed to conventional eBeam processing; namely, (1) implementation of many parallel conveyor systems in low-power facilities and (2) improved and/or automated de-palletization and re-palletization of product.

High power (~100 kW) X-ray systems for phytosanitary treatment are currently under construction in Australia and Mexico. Theoretically, the use of X-ray processing allows for pallet level irradiation treatment, thereby, avoiding the need for the excessive labor requirements that eBeam facilities need. However, the costs (capital and electricity costs) of X-ray systems can be high as compared to eBeam facilities. Also, since quick positive cash flow and a 3 to 5-year return of investment time frames are critical for the commercial success of such facilities, attention has to be paid to ensure that the facility is continuously operating. This means that there should be continuous supply of product to be treated. Given that many of these commodities are seasonal and grow at different locations within a country such as Mexico, strong cooperation among all entities in the supply chain is required. This cooperation should extend all the way from the choice of where the facility is built, the capacity, and guaranteed treatment volumes.

Location of phytosanitary treatment facilities

Globally, the use of these ionizing radiation technologies is growing the fastest for use in phytosanitary applications. The United States is the largest importer in the world of irradiated produce and Mexico is the largest exporter in the world of irradiated fresh produce. Given that phytosanitary treatment involves transboundary movement of the irradiated produce across international

borders, careful attention must be paid to the location of phytosanitary treatment facilities. Recent studies, using advanced operations management theory, have revealed the critical importance of cooperation among all the entities in the irradiated produce supply chain (Geismar et al., 2020). These studies show that with total cooperation among the different supply chain entities, overall profit increases by 8.6%. The concept of choosing the siting of phytosanitary treatment facilities based only on cursory maps of growing areas and transportation corridors and hubs can be fraught with serious financial ramifications.

Conclusions

The ionizing radiation technologies now available for the food industry include electron beam, (eBeam), X-ray and gamma irradiation. Gamma irradiation technology is slowly waning around the world. High energy eBeam (HEEB) technology is now slowly gaining market share. However, the need to bring the technology in-house has also catalyzed the commercial availability of low energy eBeam (LEEB) technology. X-ray technology-based food processing facilities are also being established to be able to treat entire pallets of food. The regulations in China and India favor large scale commercial adoption of the technology. In the United States, the sale of irradiated guavas and mangoes are expanding significantly. However, the regulations need slight modifications to enhance greater commercial adoption. Consumers do accept and purchase irradiated food all around the world. The future of this powerful technology looks promising in the food industry around the world.

Introduction

Nuclear technologies such as radioactive tracers and nucleonic gauges have been widely used in various industries to optimize processes, improve product quality, save energy and reduce pollution release. Stimulated by an ever-increasing demand from large production plants, many nuclear techniques have been evolved to provide fast and effective solutions to plant and process problems.

The basics of how radiation can be used for diagnostics and control in modern industry are covered in this chapter.

Nuclear diagnostics and process techniques

Nuclear methods, which include nucleonic analysis and control systems, radiotracing technologies and other relevant nuclear technologies, are well suited to the optimization of a wide range of modern industrial processes (IAEA, 2004, 2005). Applications from single thickness and level gauges to complex devices in the exploration, mining, and metallurgical (E3M) industries are crucial in achieving huge economic and technical benefits both now and well into the future. The nuclear techniques being deployed and expanded include the use of radioactive tracer techniques for plant optimization, particularly in flotation and leaching, XRF for elemental characterization, and PGNAA for elemental analysis on bulk samples. Other techniques, currently deployed in the laboratory, may find plant use, e.g., NAA and NMR.

Major nuclear techniques applied for diagnostics and process control are presented in the Fig. 1 (IAEA, 2004).

Radioactive tracer methodology

The basic concept for radioactive tracer methodology is injecting a radionuclide into a stream of a moving fluid and employ radiation detectors downstream to detect the movement of the subject stream. Fig. 2 illustrates the tracer injection into a process vessel (IAEA, 2008a,b—TCS-31).

Fig. 1 Major nuclear techniques applied for diagnostics and process control (IAEA, 2004).

Fig. 2 Tracer principle (IAEA, 2008a,b—TCS-31).

A tracer is any substance whose atomic or nuclear, physical or chemical properties provide for following the behavior of various physical or chemical processes. Although there are many kinds of tracers, radioactive tracers are the only ones used for online diagnosis of industrial reactors.

Radioactive tracer methodology allows the hydrodynamics of a process to be determined through the observation of the behavior of a tracing substance incorporated to the process, during its progress into or at the outlet of the system (Charlton, 1986; IAEA, 2011).

Residence time distribution (RTD)

The residence time distribution (RTD) is extremely pertinent to the operation of chemical reactors, influencing both the throughput and the quality of the product (IAEA, 2008a,b—TSC-31). The residence time distribution (RTD) measured online by a radioactive tracer is becoming an important tool for the diagnosis of industrial processing units (Fig. 3). The experimental RTD curve provides many indications for reactor troubleshooting, like parallel flows, dead space, bypass or holding up. There are many kinds of tracers; radioactive tracers are the only ones used for online diagnosis and process control (IAEA, 2008a,b—TSC-31).

Using RTD to determine hydraulic detention times in wastewater treatment ponds

The operation of a wastewater treatment installation can be deceptively complex. Given the unsatisfactory state of current theoretical approaches, there is a need to be able to assess performance practically; that is, by measuring the RTD. Modeling by RTD will be a powerful tool, aiding both the design and performance optimization of wastewater treatment systems (IAEA, 2011).

The benefits are:

- ensuring thorough treatment of wastewater, thereby safeguarding the environment,
- operating existing ponds more effectively- saving money,
- providing data for the design of future ponds.

Leak testing using radioactive tracer methods

Leak testing using radioactive tracer techniques are probably the most widespread applications of radioactive tracers in industrial troubleshooting (IAEA, 2009). Radioactive tracer techniques for leak testing are applied in petroleum and chemical process industries for both identifying, locating and quantifying the leakage in pressured vessels, heat exchangers and pipeline systems in industrial process plants.

Leaks in heat exchangers are more frequent problems in many processing plants of the petrochemical industry (Fig. 4). Radioactive tracers are very efficient and most competitive for detecting small leaks inside the heat exchangers. Detection limits as low as 0.5% of stream flow can be achieved. Radioactive tracer methods are also very effective when the pipes are buried.

Advantages of radioactive tracer technology

The main advantages of radioactive tracers compared to conventional tracers are (IAEA, 2008a,b):

Fig. 3 Residence time distribution (RTD) for troubleshooting (IAEA, 2008a,b—TSC-31).

Fig. 4 Leak detection in a heat exchanger using radioactive tracer method (IAEA, 2009).

- Radioactive tracers have high detection sensitivity for extremely small concentrations. For instance, some radionuclides may be detected in quantities as small as 10^{-17} g.
- The amounts of radioactive tracers used are virtually insignificant. For example, 1 Ci of $^{131}\text{I}^-$ weighs 8 μg , while 1 Ci of $^{82}\text{Br}^-$ weighs only 0.9 μg . That's why, when injected, they do not disturb the dynamics of the system under investigation.
- Radioactive tracers offer the possibility of in situ measurements, from the outside of a pipe or vessel. This is of special importance for many opaque industrial facilities.

Today, most of the radioisotopes employed as radioactive tracers are still produced in nuclear reactors. However, cyclotron produced radioactive tracers are increasing in frequency. Iodine-123 is an example of a cyclotron produced radionuclide with widespread availability. Radioisotope generators have been found to be particularly suitable for radioactive tracer applications in industry (IAEA, 2013).

Table 1 contains a collection of some of the most frequently used radioisotopes for tracer technology.

Nucleonic gauges

Nucleonic gauges are nuclear instruments applied for process control and analysis (IAEA, 2005). The most important applications for them are in mining and mineral processing for in situ and online elemental analysis. These groups of nucleonic gauges are more specifically named as nucleonic control systems (NCS). There are several ways of applying the NCS, among them:

- ✓ on-line (process),
- ✓ off-line (process),
- ✓ in situ (well logging),
- ✓ used in laboratory (on samples), and
- ✓ portable, for site measurements.

The principle of nucleonic gauges is given in Fig. 5.

Whenever a radiation beam interacts with matter, a fraction of it is transmitted, a fraction absorbed, and a fraction is scattered from its original path. In a transmission gauge, the media to be measured is placed between the radioactive source and the detector (Fig. 5, left). The radiation intensity in the detector is a function of several parameter characteristics of the material.

In a backscattering gauge, the scattering radiation (with angle greater than 90 degrees) emerges back from the investigated matter (Fig. 5, right) with degraded energy and intensity (count rate) characterizing the bulk density and the average chemical composition of the matter.

Table 1 Major radioisotopes used as tracer in industry (IAEA, 2008a,b—TCS-31).

Isotope	Half-life	Main energy (MeV)	Chemical form	Tracing of phase
Tritium (H-3)	12.6 years	Beta, 0.018(100%)	Tritiated water	Aqueous phase
Sodium-24	15 h	γ : 1.37 (100%) 2.75 (100%)	Sodium carbonate	Aqueous phase
Bromine-82	36 h	γ : 0.55 (70%) 1.32 (27%)	Ammonium bromide, <i>p</i> -dibrom-benzene, Dibrobiphenyl CH ₃ Br	Aqueous phase Organic phase Organic phase Gas phase
Gold-198	2.7 days	γ : 0.41 (99%)	Chloroauric acid	Solids/aqueous phases
Iodine-131	8.04 days	γ : 0.36 (80%) 0.64 (9%)	KI and NaI, Iodobenzene	Aqueous phase Organic phase
Iodine – 125	59.4 days	γ : 0.035	KI and NaI, Iodobenzene	Aqueous phase Organic phase
Iodine-123	13 h	γ : 0.159	KI and NaI, Iodobenzene	Aqueous phase Organic phase
^{99m} Tc from ⁹⁹ Mo/ ^{99m} Tc generator	6 h	γ : 0.14 (90%)	Sodium pertechnetate (TcO ₄ ⁻)	Aqueous phase
^{137m} Ba from ¹³⁷ Cs/ ^{137m} Ba generator	2.55 min	γ : 0.661	^{137m} BaCl ₂	Aqueous phase
^{113m} In from ¹¹³ Sn/ ^{113m} In generator	99.5 min	γ : 0.392	^{113m} InCl ₃ ^{113m} In-EDTA	Solid phase Aqueous phase
⁶⁸ Ga from ⁶⁸ Ge/ ⁶⁸ Ga Generator	68.3 min	γ : 1.08	⁶⁸ GaCl ₃ ⁶⁸ Ga-EDTA	Solid phase Aqueous phase
Xenon-133	5.27 days	γ : 0.08 (100%)	Xenon	Gas phase
Krypton-79	35 h	γ : 0.51 (15%)	Krypton	Gas phase
Argon-41	110 min	γ : 1.29 (99%)	Argon	Gas phase

**Fig. 5** Principles of nucleonic gauges, left transmission and right backscattering (IAEA, 2005).

Nucleonic gauges (NG) or nucleonic control systems (NCS) have been operating throughout the industrial world for quite some time. They are used by various industries to improve the quality of products by optimizing and controlling processes, saving energy and materials.

Neutron and gamma ray techniques are largely used for online analysis and control in:

- coal preparation
- coal-fired power stations
- cement manufacturing
- mineral processing and metal production
- oil industry
- density/thickness

Most of NCS are based on a few most common nuclear techniques:

- natural gamma-ray
- single energy gamma ray transmission
- dual energy gamma ray transmission
- gamma ray backscattering
- beta ray transmission
- neutron transmission
- neutron back scattering

- prompt gamma neutron activation analysis (PGNAA)

Many nucleonic gauges are now commercially available from several manufacturers. The development of supporting technologies such as compact electronics, fast computers, high-resolution detectors, small reliable neutron tubes, and dedicated computer modeling codes has resulted in increased technical viability and economic acceptability of nucleonic gauges. The development of the next generation of nucleonic devices is still taking place.

Relevant target areas are defined in international priority industrial sectors, such as oil and gas production, mining and mineral ore processing, environmental monitoring, cement and civil engineering industries, where the benefit is enormous, and the technology competes well with conventional techniques.

Industrial process gamma tomography

Industrial process gamma tomography has recently become popular in many laboratories. The gamma computer tomography (GCT) technique is the most suitable technique for visualizing the equipment contents of an opaque multiphase mixture. There are two gamma GCT methods (IAEA, 2008a,b—TECDOC-1589).

Gamma transmission tomography: The gamma transmission tomographic technique is based on the assumption that there is heterogeneity of a parameter in the system under investigation. In general, this parameter is the density of the medium. For example, determining the density of a packed bed or the concentration of a phase in a dual phase flow. There are many geometrical arrangements of source and detector(s). The simplest of these is the parallel, or pencil beam, configuration in which a source emitting a single pencil beam of radiation is coupled to a radiation detector, and this system is moved up and down surrounding the item under investigation (Fig. 6).

More complex gamma tomography systems also exist. The configuration depends upon the objectives in terms of space and time resolution. Fig. 7 shows a CT system with one ^{137}Cs source and 32 NaI (Tl) detectors (IAEA, 2009).

Gamma emission tomography: To investigate flow dynamics in multiphase flows, with or without density variations, it is generally better to use a radioactive tracer, labeling one phase and observing the behavior of this phase in the flow. Measuring radioactive tracer gamma radiation in a tomographic configuration allows the visualization of the flow patterns inside vessels to become possible.

Fig. 8 shows a gamma emission CT; 36 small NaI detectors are placed around the pipe. The radioactive tracer Tc-99 m is used and, as result, the flow image inside the pipe is obtained.

Typical fields of applications

Exploration, mining, mineral and metallurgical (E3M) industries are essential to the progress of modern society. The mining and mineral industries have contributed value-added services to the economy of many developing and developed countries. Securing a sustainable supply of raw materials is a key priority for every nation and becomes increasingly important to their economic

Fig. 6 Gamma transmission CT with 1 S—1 D (IAEA, 2008a,b—TECDOC-1589).

Fig. 7 CT system with one ^{137}Cs source and 32 NaI (TI) detectors (IAEA, 2008a,b—TECDOC-1589).

Fig. 8 Gamma emission CT (IAEA, 2008a,b—TECDOC-1589).

growth. Recent years have witnessed unprecedented growth in demands for raw materials worldwide, mainly due to rapid industrialization of emerging economies and continued material consumption (Cutmore, 2018).

In order to increase the production rates, exploitation has become more intensive over the years, which creates a variety of impacts on the environment before, during, and after mining operations. Easily accessible high-grade ore deposits are becoming less and less available over time. In many cases, high quality ores have largely been exploited and the ores remaining require more complex processing. As a consequence, mining operation has to be directed toward lower grade, deeper and/or more complex ores, which are considerably more difficult and expensive to extract. This has also led to the interest of reprocessing tailing materials.

Across the “exploration-to-product” chain, selection of the appropriate technologies for optimal recovery of the products within the process environment, their optimization for a particular system, compliance with statutory regulatory environmental conditions, as well as their implementation, are viewed as necessities.

Nucleonic gauges in mining and processing

Worldwide, new strategies and new technologies are developing and being implemented to create a translational shift in mining practice. The sensing techniques deployed and under development are wide and include both nuclear and nuclear related techniques. Some nuclear techniques are well suited to the analysis of bulk materials and play a key role in providing rapid sensing as part of an advanced systems for smart mining (Cutmore, 2018).

Neutrons provide the basis of several analysis techniques. Raw material can be analyzed by nuclear reactions, such as prompt gamma neutron activation analysis (PGNAA) and delayed gamma neutron activation analysis (DGNAA) (Fig. 9).

In the past, radioisotopes such as $^{241}\text{Am-Be}$ and ^{252}Cf have been used as source of neutrons, but these isotopes are now being replaced by intrinsically safer neutron generators (IAEA, 2012).

The PGNAA reaction (n, γ) usually happens with slow neutrons. When a slow neutron enters a material, the nucleus in the material can absorb the neutron, resulting in a compound nucleus with an excited energy that is identical to the sum of binding energy

Fig. 9 Principles of prompt gamma neutron activation analysis (PGNAA) and delayed gamma neutron activation analysis (DGNAA) (Sowerby and Cutmore, 2008).

and the kinetic energy of the neutron. This compound nucleus then proceeds to reach its ground state by emitting a prompt gamma-ray in $\sim 10^{-12}$ s. The prompt gammas can be detected, which are characteristic of the emitting element.

NAA can be caused by either slow or fast neutrons. Reactions with the target materials and fast neutrons, such as $(n,p\gamma)$, $(n,n\gamma)$, $(n,\alpha\gamma)$ produce the radioactive daughter nuclei, which is then used to find out characteristics of the target materials. PGNAA techniques have been used in field instruments, and NAA in Laboratory based systems.

Another technique about to come available to the mining industry to determine ore characteristics is Nuclear Magnetic Resonance (NMR). This technique has been widely used in medicine and other industries but not the mining industry. A radiofrequency (RF) pulse at a specified frequency is emitted into the ore, the frequency matches a resonance of a target within the ore, and an echo pulse results that in magnitude indicates the amount of target material within the ore.

This technique offers the possibility of bulk ore sorting because of the speed of the measurement. An accurate measurement can be made in less than 5 s. This would be transformational for mining. By placing a sensor onto a conveyor belt as close to the mine as possible, the sensor could first determine the average grade of the ore. The next step would use the information gained to divert the ore into three separate streams. For example, (1) a low-grade ore is tagged as waste, (2) a high-grade ore for immediate downstream processing, and (3) a medium-grade ore for stockpiling and future downstream processing. Such an analyzer has been developed for copper mines and first deployments are expected soon.

Some examples of nucleonic control systems (NCS) for online raw material elemental analysis are presented in Fig. 10.

Neutronic gauges for monitoring processes

Table 2 contains a listing of some of the more common applications.

Nucleonic gauges in paper and sheet metal manufacturing

Simple nucleonic gauges are used routinely to measure the level of liquids or solids contained in vessels in a broad range of industries, especially in temperature and high-pressure conditions. The principle of gamma-ray level gauges employed in chemical, petrochemical, petroleum, paper/pulp, and iron/steel industries is shown in Fig. 11 (IAEA, 2005).

Fig. 10 Nucleonic control systems for online raw material elemental analysis in cement and mineral ore processing (Cutmore, 2018).

Table 2 NCS applied to the exploration, exploitation and processing of natural resources (IAEA, 2005).

Techniques	Fields of application					
	Oil and gas		Logging		Mineral processing	
	Fluid flow	Delineation of deposit	In situ assaying	On and off belt analysis	Slurry analysis	Density, weight, level/fill
Natural γ radiation		X	X	X	X	X
γ -ray transmission	X			X	X	X
γ -ray backscatter		X	X	X	X	X
PGNAA and DGNAA		X	X	X		
XRF analysis			X		X	

**Fig. 11** Principle of a filling control (IAEA, 2005).

Nucleonic gauges are employed for measuring the thickness or area weight paper and metal processing industries (Fig. 12).

Soil compaction

One of the many pleasures that many of us now enjoy are good roads and highways upon which cars and trucks can traverse—even at high speeds. The key is developing a solid foundation before applying a topcoat of concrete or another preferred surfacing material. One of the principal ways to provide solid footings is to use radiation gauges to determine both the density and the moisture content of the soil beneath the foundations.

**Fig. 12** Principle of thickness monitoring using a transmission nucleonic gauge (IAEA, 2005).

A gamma source such as cesium-137 or cobalt-60 is often used for the applicable radiation gauge to determine soil density. For soil compactness measurements, the gamma source is lowered into a small test hole and the density of the soil is determined by the number of gamma rays reaching the detector at the surface. If the objective is to measure the density of thin layers of asphalt or concrete in road construction, the gamma source is placed on the surface of the layered material and the density is determined by the number of backscattered gamma rays.

For determining moisture in the soil, a neutron source, either californium-252 or a mixture of americium-241 and beryllium, is normally used. Fast neutrons, directed into the soil from the surface, are slowed after colliding with the hydrogen atoms present in the soil. A detector at the surface then records the number of thermalized (slowed) neutrons, which relates directly to the amount of soil moisture.

Mass flow dynamics in a copper melting process

In the shaft process of copper production, normally the raw materials—copper ore, concentrate and coke—are loaded continuously into the upper part of the shaft furnace. The slag and copper-matte flow from the shaft furnace into the settling tank, where the heavy phase-matte is separated from the slag (Fig. 13). For this example, a non-negligible decrease of copper recovery was observed in the copper processing line. Accordingly, a radioactive tracer experiment was incorporated to diagnose the hydrodynamics of the copper processing line (Plasari et al., 1999).

In this copper processing line, gold and cobalt are produced as copper by-products as well. Both are elements with industrial interest in copper raw mineral. The recovery of gold and cobalt was not known previous to the employment of nuclear processes. After this discovery, the radioactive tracer experiment was upgraded to measure their recovery as well. In this case, the cobalt radioactive tracer was employed with a double goal: to diagnose the process (through RTD measurement) and to measure the cobalt recovery (using mass balance method) as well. In solving this problem, the radioactive tracer technique was quite successfully applied. The Cobalt –58 radioisotope was used as the radioactive tracers in two chemical forms ^{58}CoO and ^{58}CoS (confer Figs. 14 and 15).

Fig. 14 shows the experimental RTD curves of both radioactive tracers in the shaft furnace were practically the same (were well superposed upon one another).

Fig. 15 represents the experimental RTD curves at the outlet of the settling tank and the model.

The experimental RTD curves indicate the existence of a lag (delay) and —a short circuit.

From the mean residence time of the RTD model, it was also estimated that nearly 30% of the volume of the settling tank was blocked by the solidified material. The decrease in the active volume could be one of the reasons for the short circuit. The other, not

Fig. 13 A shaft furnace and settling tank where a radioactive tracer test was carried out. D1 and D2 radiation detectors were installed at the outlet of shaft furnace and settling tank (Plasari et al., 1999).

Fig. 14 Experimental RTD curves of ^{58}CoO and ^{58}CoS at the outlet of the shaft furnace (1— ^{58}CoO , 2— ^{58}CoS , 3—model) (Plasari et al., 1999).

Fig. 15 Experimental RTD curves of ^{58}CoO and ^{58}CoS at the outlet of the settling tank (1— ^{58}CoO , 2— ^{58}CoS , 3—model) (Plasari et al., 1999).

less important response, was likely the geometrical form of the settling tank. The short circuit explains the decrease in copper recovery. In order to eliminate the short circuit, it was recommended the settling tank be reshaped.

Radioactive tracers in mineral processing

The objectives of radioactive tracer investigations in mineral ore processing industry include:

- ✓ troubleshooting
- ✓ process control and optimization
- ✓ investigation of flow patterns
- ✓ investigation of design and scale-up studies
- ✓ development/verification mathematical models.

There are certain processes found throughout mineral processing industries where radioactive tracers can be applied:

- ✓ grinding
- ✓ classification
- ✓ flotation

✓ homogenization

The most cost-intensive stage in a mineral processing plant is grinding, especially grinding, in which the ore particles are reduced in size by a combination of impact and abrasion, most commonly as a slurry.

Radioactive tracers in flotation

The use of radioactive tracers has proven to be a powerful tool to study the hydrodynamic behavior of large flotation machines (Lelinski et al., 2002). Mean residence time in pulp and froth zones can be evaluated from RTD measurements for liquid, solids and gas radioactive tracers. Relevant parameters such as mixing regime, mixing time, flow distribution in parallel flotation banks, gangue and gas entrainment, and particles segregation, have been evaluated using non-invasive sensors for radiation detection without disturbing the flotation operation. This information is fundamental for improving flotation machines operation, control and optimization.

Different radioactive tracer techniques have been used to measure a number of internal characteristics and the hydrodynamic behavior of flotation machines such as:

- residence time distribution (RTD) of liquid, solid and gas phases, in industrial cells and columns.
- real mean residence time evaluation.
- mixing regime in single cells, banks of cells and pneumatic columns.
- froth mean residence time of liquid, floatable and non-floatable solids.
- mixing time and internal pulp circulation in large industrial self-aerated cells.
- gas holdup and gas residence time distribution in flotation machines.
- flotation rate distribution.

Radioactive tracers in metallurgy

The critical raw materials, due to their high economic importance, include antimony, beryllium, cobalt, fluorspar, gallium, germanium, graphite, indium, magnesium, niobium, platinum group metals, rare earths, tantalum, and tungsten. Several other materials such as aluminium, bauxite, chromium, iron, magnesite, manganese, molybdenum, nickel, rhenium, tellurium, vanadium, and zinc may become critical as well into the near future.

The two main methods employed in order to process the ores for metal production are hydrometallurgy and pyrometallurgical process (IAEA, 2008a,b—TCS-31).

Hydrometallurgy is a technique of extractive metallurgy involving aqueous chemistry for the recovery of metals from the various raw materials such as low-grade oxide ores, concentrates, post-pyrometallurgy process tailings, electronic waste and recycled or residual materials, and other sources considered as a waste.

Radioactive tracer methods are the suitable tool for all hydrometallurgical process investigations. They provide important parameters such as:

- flow dynamics of hydrometallurgical systems,
- separation efficiency,
- process kinetics,
- process optimal time,
- agitation rate,
- liquid to solid ratio.

The *pyrometallurgy* processes involved in the mineral processing are based upon chemical reactions carried out at temperatures ranging from 500 °C to 3000 °C. The different chemical reactors that are used conventionally to carry out this process are shaft furnace, muffle furnace, hearth furnace and blast furnace. These processes may develop malfunctions with time—especially when the yield of product decreases. A huge amount of energy loss will occur if the process is carried on inefficiently in a malfunctioned reactor. Therefore, non-invasive, accurate and online techniques are required to monitor and identify any malfunction present in the pyrometallurgical reactors. Nuclear techniques (such as radioactive tracer and gamma ray densitometry) are the most suitable in these high density, large scale systems to provide various process information in the shortest possible time.

The most efficient nuclear techniques used in a laboratory setting for scaling up the design of pyrometallurgical reactors are Positron Emission Particle Tracking (PEPT) and Radioactive Particle Tracking (RPT) (IAEA, 2004). Fig. 16 illustrates the RPT method.

NCS in mining and mineral processing

Mining and mineral processing industries are the main end users of nuclear methods. Nucleonic control systems (NCS) are perhaps the most extensively employed (Cutmore, 2018). Fig. 17 illustrates some NCS applications in mining and processing industries.

Fig. 16 Principle of radioactive particle tracking (RPT) method (IAEA, 2004).

Borehole logging in search of materials

Fig. 18 (left), shows a borehole logging process for copper ore analysis in a Chile open cut copper mine using a PGNAAP probe. The calibration curve shows good correlation in the full range of concentrations from 0.2 up to 2% copper (**Fig. 18**, right). Currently, the main interest for this method focuses on the range of concentration less than 1%, in particular around 0.5%.

Looking ahead

- Nuclear techniques are now conducted internationally with bases worldwide.
- Many nuclear applications are routinely carried out on petrochemical plants, but there is now extensive involvement upstream in refining and oil/gas production.
- The current amount of business not related to oil and gas is still rather small. Many applications, particularly those offline, involving sampling, are now carried out using conventional tracers.
- However, radioactive tracers are used widely for detailed residence time and distribution studies on complex units—made possible by the availability of increasingly sophisticated data acquisition and processing systems.
- Simple nucleonic gauges are still in use for monitoring processes in industrial harsh conditions.
- There is ongoing development in designing and manufacturing complex nucleonic control systems for online applications in exploration, mining, mineral and metallurgical (E3M) industries.

Predictions for the future

- Nuclear techniques will continue to constitute an important role in Modern Industry for Diagnostics and Process Control.
- Radioactive tracer studies will become increasingly wider in scope and more detailed.
- Techniques offering process visualization, such as tomography, will be widely used.
- Neutron techniques for inspection and analysis will continue to be refined and developed.

Fig. 17 Some typical NCS applications in mining and processing industries (Cutmore, 2018).

Fig. 18 Borehole logging process for cooper ore analysis in an open cut cooper mine using PGNA probe (left) and the calibration curve (right) (Sowerby and Cutmore, 2008).

- There will be an increased uptake of the technology by industries other than oil and gas. Minerals processing appears to offer the most promise.

We should not let unjustified fear of radiation create obstacles to continued progress and benefits. There remains a clear need for more public awareness. Adherence to responsible safety guidelines remains a necessity for the application of these valuable nuclear techniques to be successfully employed.

Glossary

Bq Becquerel, – SI unit of radioactive disintegration corresponding to 1 dps (disintegration per second) with dimension s^{-1} .

Ci Curie, – previous unit of radioactive disintegration, originally corresponding to the disintegration rate of 1 g of ^{226}Ra but later modified to 3.7×10^{10} dps. It was officially replaced by Bq in 1975 but is still in use in technical texts. Thus, $1 \text{ Ci} \equiv 3.7 \times 10^{10} \text{ Bq}$, conversely $1 \text{ Bq} = 2.7 \times 10^{-11} \text{ Ci}$.

Civil Engineering A professional engineering discipline that deals with the design, construction, and maintenance of the physical and naturally built environment, including public works such as roads, bridges, canals, harbors, dams, airports, sewerage systems, pipelines, structural components of buildings, and railways.

Compton Scattering The inelastic scattering of a photon (which may be an X-ray or gamma ray photon) by a charged particle, usually an electron in an atom. The incident photon is deflected through an angle with respect to its original direction and continues in the new direction with lower energy (Compton effect).

Condition Monitoring Monitoring of the performance of processing units (multiphase separators, scrubbers, heat exchangers and similar) relative to the design criteria.

Distillation Column Scanning Identification of the internal condition of crude oil distillation unit (column) using a gamma transmission scanning technique.

Distillation Tower Identical in basic operation to distillation column or fractionating column in general. This is an essential item used in the distillation of liquid mixtures to separate the mixture into its component parts, or fractions, based on the differences in volatilities. In the petroleum industry, these columns constitute dimensions (several tens of meters) and appear as towers.

dps Disintegrations per second, dimension s^{-1} .

eV Electron volt, – energy unit used in nuclear chemistry and nuclear physics to characterize the energy of nuclear radiation and the energy of accelerated charged particles. $1 \text{ eV} \equiv$ kinetic energy gained by one electron accelerated in a potential of 1 Volt.

Gamma Emission The process whereby an excited atomic nucleus emits gamma radiation, often after beta or alpha decay, but also after having been excited by interaction of a colliding particle like a neutron or a proton.

Gamma Radiation Gamma radiation or gamma rays are high-energy photons that are emitted by decay of excited atomic nuclei. Gamma radiation is high-energy form of ionizing radiation, with very short wavelength. Energies range from a few keV to several MeV.

Gamma Scattering In civil engineering, this term is related to the Compton scattering process where Compton-scattered gamma radiation is used to reveal internal structures of the irradiated matter. The intensity of the scattered radiation tells about electron density and the energy is related to spatial position.

Gamma Tomography Based on gamma transmission, this refers to the cross-sectional imaging of an object by the use of a gamma ray source on one side and a set of detectors on the opposite side of the object. Different arrangements are possible: The source-detector arrangement may be rotated around the object or everything may be stationary but based on the simultaneous use of several gamma sources. Internal structures of the object are revealed because different materials exhibit different gamma ray transmittance (see definitions of linear and mass absorption coefficients).

Gamma Transmission In principle, gamma radiation cannot be stopped, only attenuated. The degree of attenuation depends both on atomic number Z and on material density (g/cm^3). Gamma transmission then reflects the degree to which the intensity of an original gamma ray energy has survived the transmission through an object and may, therefore, be regarded as the inverse of the gamma attenuation.

keV Kilo electronvolts $\equiv 1000 \text{ eV}$.

Injection Well This is a well in an oil or geothermal reservoir constructed to inject various liquids, liquid mixtures or gases in order to enhance the production performance of the reservoirs and/or to remove and sequester toxic or otherwise potentially polluting compounds from the industrial processes.

Isotope This term denotes nuclides of the same chemical element (same atomic number Z) but with different number of neutrons N in the nucleus. Thus, isotopes of one defined chemical element have different mass numbers A since $A = Z + N$. Some isotopes of such a defined chemical element may be stable and some radioactive (most often artificially produced). Example of isotopes of cobalt ${}^A_Z\text{Co}_N$: ${}^{59}_{27}\text{Co}_{32}$ or only ${}^{59}\text{Co}$ (stable) and ${}^{60}_{27}\text{Co}_{33}$ or only ${}^{60}\text{Co}$ (radioactive).

Linear Absorption Coefficient The fraction of a beam of a defined gamma radiation energy absorbed per unit thickness (cm) of an absorber, dimension cm^{-1} .

Mass Absorption Coefficients The linear absorption coefficient divided by the density (ρ in g/cm^3) of the absorber, dimension cm^2/g .

MeV Million electronvolts $\equiv 1000.000 \text{ eV}$.

Mineral Scaling Precipitation of a mineral salt in a liquid due to oversaturation of one or more of the ionic components involved, – see definitions of solubility product and saturation ratio. Examples of mineral scaling experienced in the oil, geothermal and water production are: CaCO_3 , BaSO_4 , FeS and more.

Multiphase Flow Metering Monitoring of individual components of aqueous, oleic and gas fluids and solids in a continuous flow.

Nuclide An atomic nucleus is defined by its atomic number Z (number of protons, which defines the chemical element) and its neutron number N . It is illustrated by the symbol ${}^A_Z\text{X}_N$ where $A = Z + N =$ the mass number. For a known chemical element, say cobalt, we know that $Z = 27$. For a unique definition of the nuclide, notation of the mass number and the chemical symbol are sufficient, i.e. ${}^{60}\text{Co}$ is a uniquely defined nuclide.

PET Positron Emission Tomography is an imaging procedure that uses radionuclides emitting positrons to create 3-D pictures of the object in which it has been introduced. It is based on annihilation of the positron whereby two photon quanta, each of an energy of 511 keV, is generated and emitted with an angle of 180 degrees.

Porous Media Generally speaking, these are solid materials containing pores (voids). The skeletal portion of the material is often called the “matrix.” In the present context, the solid materials are minerals or mineral compositions of different kind, and the pores are typically filled with a fluid (liquid or gas).

Positron Positively charged electron emitted from a radioactive nucleus.

Production Well Well drilled into a reservoir for production of reservoir fluids (oil, gas, water, steam etc.).

Radionuclide A radioactive nuclide.

Reaction Kinetics In this context the term is concerned with understanding the rates of chemical reactions. Chemical reaction kinetics includes investigations of how various experimental conditions (temperature, pressure pH, chemical component concentrations etc.) influence the speed of a chemical reaction.

Reservoir Rock Porous rocks that have the ability to store fluids inside their pores. Accordingly, fluids like water, oil, and gas can be accumulated and transported. In petroleum geology, such rocks are mainly based on sandstones or carbonates. In the geothermal fields, fractionated granite rocks also belong to this category.

Saturation Ratio (SR) For a specific uncharged inorganic compound C_xA_y ($\text{C} =$ cation, $\text{A} =$ anion) saturation ratio is defined as $\text{SR} = [\text{C}]^x \cdot [\text{A}]^y / K_{\text{sp}}(\text{C}_x\text{A}_y)$; see definition of solubility product, K_{sp} , below. For $\text{SR} < 1$, no precipitation can happen. For $\text{SR} = 1$, onset of precipitation is thermodynamically allowed, for $\text{SR} > 1$, precipitation will take place.

Scaling Inhibitor A class of specialty chemicals that are used to slow down (kinetic inhibitor) or prevent (thermodynamic inhibitor) mineral scaling in water systems.

Solubility Product Cations and anions may combine to non-charged compounds which, in solution, may precipitate as a solid phase in equilibrium with dissolved ions. The concentration of cations and anions in this equilibrium defines a physical parameter known as the solubility product, K_{sp} . For the reaction $C_xA_y \rightleftharpoons xC + yA$ the $K_{sp} = [C]^x \cdot [A]^y$, where the brackets denote the concentrations. Each noncharged (salt) compound has a specific K_{sp} -value for defined experimental conditions. Examples for aqueous solutions at 25 °C: $K_{sp}(\text{CaCO}_3) = 3.3 \times 10^{-9} \text{ mol}^2$, $K_{sp}(\text{FeS}) = 4.9 \times 10^{-18} \text{ mol}^2$.

SPECT Single Photon Emission Computed Tomography is based on the use of radionuclides that emit single photons (as opposed to PET radionuclides) to picture activity distribution in an extended object. In its simplest version, a projection only is recorded. By recording projections at different angles, a 3D tomographic picture may be generated.

Three-Phase Flow Separator In this context, a processing device that enables separation of the single components water, oil and gas from commingled production in production wells.

TOF Time-of flight is the measurement of the time taken by an object, particle (for instance a neutron) or a wave (for instance electromagnetic) to travel a distance through vacuum or a medium.

X-ray Electromagnetic radiation where one may differentiate between two forms based on their different origin: 1. The elementary X-rays that originate from the electron shell structure in an atom with a definite narrow energy bands (specific for each chemical element) and with energies in the eV and keV range, and 2. the so-called bremsstrahlung, which is generated by charged particles, in practice electrons, accelerated (or bent) in an electromagnetic field. This latter "type" has a continuous energy distribution without definite structure with energies from eV to several tens of MeV, depending on the kinetic energy of the accelerated particle.

Introduction

This chapter describes the principles and practical uses of gamma radiation, i.e. gamma transmission, gamma scattering, gamma tomography and x-ray tomography methods in materials testing and inspection.

Gamma radiation originates from the atomic nucleus. When a nucleus at high excitation de-excites to lower energy states, gamma radiation is emitted. Such highly excited states may be populated in the decay process of radioactive nuclei and by induced nuclear reactions of different kinds. Gamma energy spectra consist of discrete peaks (photo peaks) on a ridge of scattered (Compton) radiation. X-rays may be regarded as a collective term composed of *elementary x-rays* originating from deexcitations in the electron structure around an atomic nucleus with discrete energies, and of *bremsstrahlung*, which occurs by fast acceleration of charged particles. The latter produces a continuous electromagnetic energy spectrum with no discrete structure. The energy distribution depends on the kinetic energy of the charged particles. This happens for instance when an electron passes through the electromagnetic field of an atomic nucleus or when a fast-moving electron beam is bent in an external electromagnetic field like in a ring-shaped accelerator (synchrotron radiation).

Gamma energies and x-ray energies are measured in electron volts, eV.¹ Gamma energies range normally from a few keV (kilo electron volts) to several MeV (million electron volts). Energies of elementary x-rays range from 54.3 eV for lithium ($K_{\alpha 1}$ -line) to 114.5 keV for uranium ($K_{\beta 2}$ -line) while bremsstrahlung energies may have maximum energies of several tens of MeV.

Gamma transmission and scattering

The gamma transmission method

This is a non-destructive and non-intrusive method to measure mass density or mass thickness (g/cm^2) of an object. Gamma radiation from an external gamma source penetrates the object, and the decrease in intensity, or the gamma attenuation over the object, is measured. We may, somewhat imprecisely, call it the principle for "the nuclear scale or the nuclear balance". The principle of this method is illustrated in Fig. 1A.

Transmission of a mono-energetic beam of collimated photons through a single and uniform absorption sample can be described by Lambert-Beer's equation

$$I_{xA} = I_0 \cdot e^{-\mu_A x_A} \quad (1)$$

where I_0 is the beam intensity before transmission, I_{xA} the beam intensity after transmission, μ_A the linear absorption coefficient of the absorbing material A with dimension cm^{-1} and x_A the material thickness (cm).

When the sample is composed of several materials, say A, B and C, each with their own linear absorption coefficients μ_A , μ_B and μ_C and thicknesses x_A , x_B and x_C , exponents are additive, and the formula becomes (Fig. 1B)

$$I_{x_A x_B x_C} = I_0 \cdot e^{-(\mu_A x_A + \mu_B x_B + \mu_C x_C)} \quad (2)$$

¹1 eV = the kinetic energy attained by an electron accelerated in a potential of 1 V.

Fig. 1 Gamma transmission measurement principle illustrated on a single sample in (A), and on a composite sample in (B).

More frequently used than the linear absorption coefficients are perhaps the *mass absorption coefficients* defined as μ/ρ with dimension cm^2/g . Here, ρ is the material density (g/cm^3). Let us call this parameter μ_m . The corresponding x -parameter is then the *mass thickness* denoted with x_m , and with dimension g/cm^2 . Introducing this parameter into Eq. (2) gives:

$$I_{x_A x_B x_C} = I_0 \cdot e^{-(\mu_{mA} x_{mA} + \mu_{mB} x_{mB} + \mu_{mC} x_{mC})} \quad (3)$$

The relation between the linear thickness and the mass thickness is simply $x = x_m/\rho$.

Mass absorption coefficients for various chemical elements (and for many common compounds) are tabulated in (Hubbell and Seltzer, 2004). Values vary with gamma energies as illustrated in Fig. 2 below for aluminum, copper and lead.

Often, it is illustrative and informative to derive the thickness needed of a selected material to reduce the transmitted intensity to half the value of the initial intensity, – the so-called half-value thickness (HVT) or $x_{1/2}$. The procedure is as follows:

Eq. (1) may be rewritten as

$$\mu_m = \frac{\mu}{\rho} = \frac{\ln(I_0/I_x)}{x_m} \quad (4)$$

Solving for x_m and setting $I_x = I_0/2$ gives:

$$x_m = \frac{\ln(2)}{\mu/\rho} \quad (5)$$

Dividing this expression with the material specific density ρ gives the half-value thickness $x_{1/2}$.

Examples of such calculations for the three chemical absorber elements Al, Cu and Pb, and for gamma energies from the three radionuclides ^{241}Am , ^{192}Ir and ^{137}Cs are given in Table 1.

The gamma scattering method

This method relies on the Compton effect, where a gamma ray transfers parts of its energy to an atomic electron in the gamma ray path and is scattered away in an angle different from the incoming direction and with a lower energy $E'_\gamma = E_\gamma - E_e - E_{eb}$. Here, E_γ is the incoming gamma energy, E_e the energy transferred to the dispatched electron and E_{eb} the binding energy of the electron in the atom. This method is further explained in the applications section below.

These technologies are useful and utilized both in hand-held, transportable and stationary (permanently mounted) instruments with a wide range of applications. The radioactive sources used in this kind of equipment are medium and low activity sealed sources in the range of 10–100 MBq. Typical radionuclides are ^{241}Am (60 keV), ^{137}Cs (661 keV), and ^{60}Co (1174 and 1332 keV),

Fig. 2 Mass attenuation coefficients as a function of gamma energies for the three metals aluminum (Al), copper (Cu) and lead (Pb). The curves are derived on the basis of tabulated values from (Hubbell and Seltzer, 2004).

Table 1 Calculated values of mass thickness and half-value thickness of dominant gamma radiation from three radionuclides often used in practical gamma transmission measurements for the three metals Al, Cu and Pb.

Radionuclides		²⁴¹ Am (60 keV)				¹⁹² Ir (317 keV) ^a			¹³⁷ Cs (661 keV)		
Element	ρ (g/cm ³)	μ/ρ (cm ² /g)	x _m (g/cm ²)	x _{1/2} (cm)	μ/ρ (cm ² /g)	x _m (g/cm ²)	x _{1/2} (cm)	μ/ρ (cm ² /g)	x _m (g/cm ²)	x _{1/2} (cm)	
Al	2.699	0.278	2.50	0.92	0.100	6.93	2.60	0.075	9.24	3.42

^aEvaluated only for the strongest gamma line of 317 keV (82.9%) and not for the second strongest of 468 keV (47.8%).

depending on the individual application. The purchase, handling and use of such sources must be approved by the appropriate radiation protection authority in accordance with radiation protection regulations, and the practitioners must be licensed.

The practical use of this gamma transmission method, briefly outlined above, is best demonstrated by showing some examples of applications in science, industry and civil engineering.

Various application examples

Applications in civil engineering

Soil compaction and asphalt thickness

Nuclear density gauges are used by many building contractors, engineers and highway departments for compaction control of soil, aggregate, concrete and asphalt. They are used to determine compaction acceptance of earthworks, granular and stabilized pavement materials, concrete and asphalt (Whitepaper, 2020; APNGA Manual, 2009; IAEA, 2005). This means that buildings and roads are only as good as the foundations you build them upon, and this must be carefully controlled during building site and road preparation and construction.

Wet density, also known as bulk density, typically consists of the soils and moisture present in the ground being compacted. Dry density consists of only the soil solids. The most stable foundation consists of a mixture of solids and moisture. The key to

maximum density and stability is the percentage of moisture in a given soil. The moisture acts as a bond or “glue” for the soil particles. If the moisture is too high, the water will displace the denser soil particles. Hence, no bonding will occur, and a maximum compaction of the particles is not possible. One may end up with mud. If the soil is too dry one will lose the stabilizing effect of the moisture. The needed humidity for maximum soil stability varies with the type of soil.

In order to determine the soil density and humidity, various nuclear gauges have been constructed. These are commercially available today in several designs. They are based on the principles of gamma transmission and gamma scattering (Compton scattering) for density measurements and on neutron back-diffusion (or backscattering) for measurements of humidity. The gamma scattering principle is discussed below while the neutron back-diffusion method is treated in (Bjørnstad, 2021).

The gauge principle sketched in Fig. 3 consists of a shielded and sealed gamma-emitting radioactive source, detectors for gamma radiation and electronics to convert count rates to information. These conversion routines are based on a thorough laboratory calibration for various types of soil, humidity and pavement.

The source most often used is ^{137}Cs (661 keV) with a source strength in the region 200–400 MBq. In the simplest versions the detector is a Geiger-Muller tube.

In the direct transmission position the source rod extends through the base of the gauge into a predrilled hole up to 30 cm deep in the material being tested. The gamma rays from the source, penetrate the test material, are attenuated and subsequently counted by the detectors located within the gauge. The average density between the source and detectors is then determined.

When in use, this instrument is placed on top of the road surface at a position which has been carefully prepared. It can be operated in various modes, two of which are the soil mode and the asphalt mode. Operational parameters and calibration factors vary between the modes.

Soil mode is designed for measurements of soils, stone or other materials where both density and moisture content are desired. Direct transmission testing typically offers better precision and control of depth of measurement and is the preferred method.

Asphalt Mode is used to depths greater than 100 mm of asphalt. Typically, the source rod is in the backscatter position, i.e. slightly above the asphalt (see Fig. 4), but direct transmission can also be used if a hole can be drilled in the asphalt. After having carefully prepared the measurement site, the measurement itself takes only a few minutes. The measurement precision is good (<1%) but the accuracy may vary depending on operational performance and generation and application of correct calibration parameters.

Neither the source nor the detector is directionally collimated. This means that scattered radiation (Compton scattering) will be obtained from various positions and depths over a broad energy range. This enhances the sensitivity but diminishes the specificity, i.e. the sensitivity to special positions.

The energy of the scattered radiation depends on the scatter angle θ as defined by Eq. (6).

Here, E_γ is the emitted gamma energy from the source, E'_γ the energy of the scattered gamma quantum, θ the scattering angle (see Fig. 5), m_e the electron rest mass and c the speed of light. The factor $m_e c^2 = 511$ keV.

Fig. 3 Portable density gauge based on gamma transmission and scattering, here shown operating in the gamma transmission mode.

Fig. 4 Portable density gauge based on gamma transmission and scattering, here shown operating in the gamma scattering mode.

Fig. 5 Collimated source and detector showing the scattering angle θ , and where the angle ϕ can be varied.

$$E'_\gamma = \frac{E_\gamma}{1 + \frac{E_\gamma}{m_e c^2} (1 - \cos\theta)} = \frac{E_\gamma}{1 + \frac{E_\gamma}{511} (1 - \cos\theta)} \quad (6)$$

A more narrowly defined Compton-scattered gamma energy is detected. The energy of the scattered gamma ray can be calculated by Eq. (6). Varying the angle ϕ gives possibility of depth information. All equipment is above ground. By moving this surface equipment laterally in a predefined pattern, volumetric information may be retrieved. This is not readily possible with the equipment sketched in Fig. 4 and not practical with equipment pictured in Fig. 3.

Sediment studies in harbors

The investigation of sediment transport along seashores and in rivers is important for civil engineering and coast-near protection and management (Wentworth, 1922; Maa et al., 2006; Dyer, 1986; Corporate author, 2015). Littoral regions (along the shores) and sea beds are in dynamic change. Coastlines are undergoing periods of erosion with sediment transport, sedimentation and consolidation. The main causes for erosion in beaches include:

- storms leading to ocean waves that attack the consolidated coastline rock and, with time, breaks it down into grains and fines,
- human actions, such as the construction of quays and seawalls,
- jetting and the dredging of river mouths followed by dumping of the dredging deposit.

Each of these human actions disrupts the natural flow of sand. Current development activities and practices are accelerating the beach erosion process. However, there are viable options available to study the development of such disruptions in order to mitigate the damage and to provide for sustainable coastline control.

One useful method is the application of radiotracers for sediment transport studies (IAEA, 2014). Sealed source techniques can also provide information on the density of sediments deposited in a channel of navigation, as well as on the concentration of sediments circulating in suspension.

Sediment studies in seas, rivers and dams commonly deal with sand and silt. There are different sub-classifications of sands according to their sizes. The most widely used classification of sediments and sedimentary particles is the Wentworth's classification (Wentworth, 1922). It comprises four main classes of particles:

1. Gravel: particles greater than 2 mm (mm) in diameter;
2. Sand: particles between 63 μm (μm) and 2 mm in diameter;
3. Silt: particles between 2 μm and 63 μm in diameter; and
4. Clay: particles less than 2 μm in diameter.

Sedimentation and sediment density may be studied in controlled laboratory examination in two ways: (1) Directly on sediment columns extracted from the sea floor by specially designed sampling equipment in order to preserve the natural axial composition and density variation, and (2) on a sediment slurry that is set to sediment in the laboratory in order to measure sedimentation rates. Mud compaction rates, their initial concentration, height of the deposit and the salinity of the medium can be investigated in this way by a nucleonic gauge using gamma transmission. For this purpose, a source of ^{241}Am (3,7 GBq) may be positioned opposite a carefully collimated scintillation detector with the column in the middle. The source-detector pair can be scanned axially over the column to record the changing density with column height. Density precisions in the order of 1% may be obtained in term of concentration of the mixture at one moment and on a given level (Meyer et al., 1983).

However, useful in-situ information can also be obtained by realistic studies directly on the various costal sites of interest by using real-time NDT-methods. Three methods are

1. Gamma ray scattering

Here, a measurement tool consisting of a radioactive source and a gamma ray detector sealed in a water-proof housing is lowered by a wireline from a boat down towards the seabed where the tool sinks some distance into the sediments. The density of the surrounding sediment is measured by the gamma scattering technique as illustrated in Fig. 6. The source is typically ^{137}Cs (661 keV) with a strength of 18.5 MBq. The detector has spectroscopic properties and consists typically of a 50x50 mm NaI(Tl) crystal.

Fig. 6 Principle of a gamma ray scattering gauge designed for in-situ measurement of seabed sediment density and thickness.

2. Gamma ray transmission

A typical example of an instrumentation that can be moved, in principle, continuously over large areas is illustrated in Fig. 7. It consists of a sledge which is towed on the seabed behind a boat on the water surface. The sledge contains a gamma source (source type ^{241}Am or ^{137}Cs , source strength $\approx 220\text{ MBq}$) on one skid beam and a spectroscopic gamma detector (typically a $50\times 50\text{ mm NaI(Tl)}$ crystal) on the other skid beam. The space in-between will automatically be filled with sediments during operation. The measurement method is thus based on the gamma transmission principle. The layout of the sledge can be modified in order to account for various sediment, slurry or dispersion densities which may also need adjustment in the type and activity of the radioactive source.

The boat may traverse the sea in a defined pattern. Thus, extended areas can be monitored with reduced effort.

3. X-ray transmission

This technique is very similar to the gamma transmission technique but characterized by lower energy photons generated by an X-ray tube instead of a radioactive source. Typical photon energies are in the order of 30 keV . The tool itself consists of two parallel vertical legs with a spacing, one containing the X-ray generator and the other the x-ray detector in a very robust design. The tool is lowered stepwise down towards the seabed and finally into the sediments while measurements are recorded continuously. Thus, changing density is measured in a vertical setting. In order to map sediment densities over an area, the tool must be relocated to another position in a preselected grid pattern.

Examples of practical applications of sediment studies with nuclear-based methods are found in refs. (Crickmore et al. (1990) and Bandeira et al. (2014).

Applications in science

The examples are multiple, but we will here limit the description to only one example, – the laboratory-based studies of the basic mechanism of undesired mineral precipitation, or *scaling*, in various process equipment. This is a major concern both in civil engineering (clogging water supply systems) and various industries like the oil production industry (reduces permeability in the mineral rock close to production well and thereby the production rate, clogs production tubes and affects negatively the performance of 3-phase separators) and the geothermal energy production industry (clogging production wells, heat exchangers and valves). The costs for maintenance and replacement of vital equipment parts and components amount to billions of dollars each year. Hence, there is a considerable drive to understand the basic scaling mechanisms in order to come up with effective mitigation measures.

Study of mineral scaling and scaling kinetics

Natural waters contain cations and anions of different kinds. When the concentration of some of these ions in combination surpasses certain limits, precipitation of solid compounds takes place.

The solubility of a certain solid compound is defined by its solubility product K_{sp} . For a compound with the general formula C_xA_y the stoichiometric solubility product is defined as $K_{sp} = [C^{y+}]_{eq}^x \cdot [A^{x-}]_{eq}^y$ where $[C^{y+}]_{eq}$ and $[A^{x-}]_{eq}$ are the concentrations in mol/L of the cation and anion of the compound, respectively, at saturation, i.e. in equilibrium with the solid compound C_xA_y . The solubility product depends on temperature, pressure, ion strength etc. Hence, precipitation requires that the actual

Fig. 7 Sketch of a sledge equipped with a collimated gamma source and a collimated scintillation detector for gamma transmission measurements of the sediments/sludges directly on the seabed as the sledge is towed behind a boat on the surface (illustration modified after ref. IAEA, 2005).

and real ion product in the water present $[C^{y+}]^x \cdot [A^{x-}]^y > K_{sp}$ for the existing conditions. This is expressed as the saturation ratio SR defined in Eq. (7):

$$SR = \frac{[C^{y+}]^x \cdot [A^{x-}]^y}{K_{sp}} > 1 \quad (7)$$

If $SR < 1$ we say that the solution is undersaturated and precipitation cannot take place.

There are several cations which, in combination with certain anions, may result in scaling leading to process equipment component fouling, see Fig. 8. Examples are Ca^{2+} , Sr^{2+} and Ba^{2+} in combination with CO_3^{2-} or SO_4^{2-} and Pb^{2+} , Zn^{2+} and Fe^{2+} in combination with CO_3^{2-} or S^{2-} . The main scaling type in fresh-water supply systems, especially in ground waters, is $CaCO_3$. In the petroleum sector the main scaling components are $CaCO_3$ (high), $SrCO_3$, $BaCO_3$, $FeCO_3$, $BaSO_4$ (high), FeS , ZnS and PbS . In the geothermal sector the main scale components are $CaCO_3$ (high), FeS , ZnS , PbS and, in high-temperature geothermal reservoirs ($T > 300^\circ C$), amorphous silica $[SiO_x]_y$ (high), which originate from dissolution of silicate minerals in the reservoir rock.

In the further text we will concentrate on $CaCO_3$ scaling. Aspects about the precipitation mechanism can be studied in dedicated laboratory experiments by nuclear techniques including gamma transmission.

Waters of different origin contain considerable amounts of calcium and bicarbonate ions. Although the ions are in equilibrium in the reservoirs, during the production and the associated pressure release downstream in the production tubing, bicarbonate decomposes into carbonate and CO_2 . If Ca^{2+} is present in sufficient concentration, $CaCO_3$ will precipitate according to the equation:

The scaling mechanism and rate (kinetics) can be studied partly with a setup as sketched in Fig. 9 (Bjørnstad and Stamatakis, 2006). Here, separate liquid flows of calcium (Ca^{2+}) and bicarbonate (HCO_3^-) representing $SR > 1$ meet in the fluid mixing

Fig. 8 Water transportation tubings nearly blocked by $CaCO_3$ precipitation.

Fig. 9 Sketch of a gamma transmission setup to study mechanism and kinetics for precipitation of calcium carbonate, $CaCO_3$.

zone. Creation of tiny precipitation seeds will start immediately. Most of the seeds will be transported down-stream but some will attach to the flowline wall at the mixing zone. Here, they act as crystallization points for further particle growth, and a solid layer will start forming and continue growing on the inner wall at the mixing zone and further downstream as well. A stationary setup of a radioactive source (^{133}Ba) and a gamma detector monitors the mixing zone and the increasing mass of the formed scale by a decrease in the recorded count rate. The thickness of the scale can be calculated by Eq. (2) above, when we introduced the values of the linear attenuation coefficients μ for aluminum, calcium carbonate scale and brine that have been measured separately. The thickness of the aluminum walls is constant, and the known internal diameter is $x_{\text{scale}} + x_{\text{brine}} = 10 \text{ mm}$. Hence, $x_{\text{brine}} = 1 - x_{\text{scale}}$ and Eq. (2) may be solved with respect to the only unknown parameter x_{scale} . In this way one can study the precipitation reaction kinetics for changes in various parameters like temperature, concentrations of the precipitating components, effect of other ions present in natural waters (brines) and of various production chemicals that are often added to the industrial processes like, for instance, corrosion inhibitors.

But perhaps most important is the effect of adding chemicals to try to prevent the precipitation to take place, so-called scaling inhibitors. That is the main technical aim of such studies. Fig. 10 illustrates the effect of adding one possible scaling inhibitor in different concentrations to one of the liquid flows in a system where $\text{SR} = 20$. Scaling is significantly reduced with increasing inhibitor concentration, and at 100 ppm (ppm) no scaling and scale growth has been detected at the fluids mixing zone. This method can be used to investigate the effect of various scaling inhibitors in order to find the best alternative, which is a function of the lowest possible concentration, lowest environmental impact and lowest price.

Applications in the oil industry

There are multiple applications of the gamma transmission technique in the petroleum production industry (see also Thereska, 2021). Here, we will briefly touch upon four applications: 3-phase fluid separator condition monitoring, 3-phase flow separator separation performance, distillation tower condition monitoring, and multiphase flow metering.

3-Phase fluid separator condition monitoring

In general, oil well fluid flow consists of the three fluids oil, water and gas, but the flow may also contain suspended particles like sand from the reservoir and scaling as described above. The components are separated into individual phases in a 3-phase flow separator. Suspended particles settle at the bottom. The immiscible components (on the molecular level) oil and gas separates normally with water at the bottom and oil on top and is drained from the separator through different channels. Gas exits the separator at the top. Each of the phases continues to further purification steps: Oil to remove traces of emulgated water, water to remove traces of emulgated oil and, in some cases, water-dissolvable organic components originating from the oil, and gas to remove traces of wetness consisting of water and organic gaseous molecules with carbon number higher than about 4 (butane).

With time, performance of the separator may deteriorate; for instance, due to changes in the internal structure because of corrosion and mechanical breakdown or to accumulation of too much solid particles. Using gamma transmission monitoring, problems of this nature may be detected, calling for major maintenance.

Multiphase separators are mechanical structures that come in different configurations and sizes. A simple outline of a horizontal multiphase separator is sketched in Fig. 11. On offshore oil production rigs, these structures are large, i.e. more than 10 m long and

Fig. 10 Decrease in growth of scaling thickness with increasing concentration of an added scaling inhibitor.

Fig. 11 Sketch of a multiphase separator for oil, water and gas and the use of a scanning setup of a gamma transmission monitoring equipment to detect operational anomalies.

Fig. 12 Off-shore field installation of a gamma source below a 3-phase separator for gamma transmission monitoring experiments. Mind the sizable dimensions.

3–4 m in diameter. A radioactive source below the separator tank (Fig. 12) and a corresponding gamma detector above the tank are scanned along the tank axis direction to record densities and detect any possible change in the internal metallic structures. Typical sources are ^{137}Cs (661 keV) and ^{60}Co (1174 and 1332 keV) with activities of a fraction of GBq up to some tens of a GBq.

3-Phase flow separator separation performance

Performance of a separator depends not only on the separator construction itself but also on molecular components and their concentrations in the incoming fluid mixture. Throughout the lifetime of an oil reservoir (20–40 years, sometimes longer) the natural compositions of oil, water and gas change. In addition, as reservoirs age, improved oil recovery methods are sometimes applied to keep up the production volume as long as possible. This implies that so-called production chemicals are injected into reservoirs and wells in relatively large amounts. Such chemicals comprise corrosion and scaling inhibitors and acids for wells, and polymers, surfactants and alkaline solutions for reservoirs. Some fraction of these chemicals enters the separator as well and may contribute to perturbation of the normal operational regime. Therefore, it is important to follow tightly the separator performance by frequently monitoring the level of the various phases in the separator, which, in addition to those already mentioned, contains an oil/water emulsion phase and an oil-gas foam phase. Equipment with different designs have been constructed based either on gamma transmission or neutron back-diffusion (backscattering) technology. The latter is treated further elsewhere on neutron methods (Bjørnstad, 2021).

Fig. 13 Principle sketch of Tracerco's "density profiler" mounted in a horizontal 3-phase separator measuring the density profile (height) of the various phases inside the separator during operation.

Fig. 14 Illustration from an oil refinery showing distillation columns of various sizes.

Fig. 13 shows a principle sketch of an equipment developed by Tracerco² (Charlton, 2006). It consists of two parallel and vertically mounted titanium pipes with a spacing of a few cm. One pipe contains a set of ^{241}Am -sources in tungsten shielding facing a set of opposite detectors (Geiger-Muller (GM) tubes) in the other pipe. The number of source-detector pairs depends on the desired vertical measurement resolution and the diameter of the separator. The tubes may contain up to a maximum of 125 units. The monitoring unit is inserted into the separator from the top so that the pipes stick into the fluids all the way down to the bottom. The expanded view to the left in **Fig. 13** shows how the collimated radiation from the source penetrates the medium between the pipes and is detected by the collimated GM-tubes. The count rate is recorded for each source-detector pair whose individual characteristics are calibrated. It depends on the density of the traversed medium. Low count-rate means high density and higher count rate lower density. The composite results are shown as the relative counting rates in the panel to the right in **Fig. 13**. The instrument is continuously operating, but in practice the panel showing the relative counting rate is updated in intervals (counting times) at frequencies chosen by the operator from seconds and upwards. Such a surveillance gives the operator insight in when to modify the various running conditions like the flow rates and chemistry in order to rectify any malfunctions.

Distillation tower condition monitoring

Oil from the 3-phase separators described above is piped downstream for further processing. This processing is of various kinds: distillation to separate components, cracking to chop up long-chain compounds into smaller, chemical conversion to produce new compounds, etc. The present section will be limited to monitoring of distillation columns.

In an oil refinery, several types of columns are in operation. Two main types are trayed and packed columns. The sizes of the mechanical structures vary, from ~ 10 m up to >100 m in height and with diameters from ~ 2 to >10 m (see **Fig. 14**). In

²www.tracerco.com.

a distillation process, the molecular components are separated based on the *relative volatility* of the components. The relative volatility of component *a* relative to component *b* is defined as

$$\alpha_{ab} = \frac{x_{va}/x_{la}}{x_{vb}/x_{lb}} \quad (8)$$

where x_{va} is the mole fraction of component *a* in the vapor phase, x_{la} is the mole fraction of component *a* in the liquid phase x_{vb} and x_{lb} the corresponding mole fractions for component *b*.

The atmospheric distillation columns belong to the biggest units. They can process up to $> 30,000 \text{ m}^3$ of oil per day. The process pressure is slightly above atmospheric pressure.

A distillation column like the one sketched above is, of course, not able to resolve single components into individual fractions. Rather, boiling point fractions along the height of the column are collected with the least volatile in the bottom and the most volatile (like methane = C1, ethane = C2 etc.) at the top.

This is illustrated in Fig. 15. These fractions include methane, ethane, propane and butane mixtures, naphtha's/gasoline fractions, kerosene/aviation turbine fuel, light oil like diesel, heavy oil like lubrication oil and fuel oil for ships and so-called reduced crude oil (the least volatile fraction), which are further processed in vacuum distillation columns.

In a trayed column during normal operation, each tray should sustain an adequate liquid loading. If the operation shows that results deviate from the design output, the reason is often that the liquid loading in individual trays or in tray sections are too large (flooding) or too low, which again may be due to mechanical changes in the internal structure of the column. The incoming crude oil contains acidic components like CO_2 and H_2S , although to varying degrees. Over time these may attack internal steel structures, especially at high temperatures, and trays may be damaged.

Gamma transmission scanning is a useful method to identify reasons for such deteriorated separation efficiencies. These scans are carried out during full tower operation and enables detection of the problem in "true time" while it is being experienced. Flooding, entrainment, foaming or weeping (liquids drop downwards from tray to tray) may be detected together with any major

Fig. 15 Illustration of an atmospheric pressure distillation column where the preheated crude oil from the 3-phase separator enters near the bottom. The molecular components are separated according to their volatility which is related to the number of carbon atoms (C₁, C₂, C₃ etc.) in the molecules.

mechanical structure defects (Hills et al., 2002; Abdullah, 2005; Laraki et al., 2008; Walinjkar and Singh, 2011; Elsharkawy and Hammad, 2018).

A gamma scan is performed by positioning a gamma source placed in a 360° panoramic lead collimator (normally ^{137}Cs or ^{60}Co , source strength in the range 30–100 MBq) on one side of the column and a directional lead-collimated detector (normally NaI(Tl) scintillator) on the opposite side (see Fig. 16). The source and detector are aligned at the top of the column and synchronously lowered down the outside of the column in steps where counting rate recordings are taken for every step. The orientation is normally chosen to scan the column diameter or through another selected active area. The gamma attenuation is strictly dependent on the density of the material between the source and detector. The major factor affecting the amount of radiation passing through the column apart from the mechanical structure is the presence of liquid on the trays and the absence of liquid in the vapor spaces.

Repeating scans under different operating conditions such as temperature, pressure, feed flow rate and reflux ratios can reveal additional information on the degree of entrainment (carry-over of liquid), tray and “jet” flooding and foaming or “weeping.” However, often only one scan is performed to detect a malfunction.

In principle, two preparative scans should be performed on all columns: One before liquids is introduced to obtain a “background” density chart of the mechanical structure, and one after the column has come into normal operation right after commissioning of the column. These scans will then represent the normal operating conditions and will later ease the interpretation of a scan taken during some form of malfunction.

For packed columns, four scans are often performed (see Fig. 17) to detect malfunctions like packing material collapse or other types of heterogeneous redistribution, which affects the column performance.

Multiphase flow metering

Multiphase systems are fundamental to the operation of many industrial and environmental processes. They are to be found across a very wide industrial spectrum, embracing various types and sizes of production unit ranging from oil production facilities at one extreme, with throughputs of tens of thousands of tons per day, to pharmaceutical plants, with throughputs of the order of a few tons per day, at the other.

Generally speaking, it is large-scale and continuously operating units that are the main beneficiaries from radionuclide applications. Because of the sheer size of the processes, the economic benefits arising from on-line troubleshooting and basic process optimization procedures, such as de-bottlenecking are often very large, and this has acted as an incentive for large-scale industries to utilize the technology extensively. For this reason, these industries have long been the main target area for the exploitation of various radionuclide techniques of which gamma transmission monitoring is one.

Here, we will exemplify the usefulness of this technique by limiting the text to applications in the oil and gas sector (production, treatment and pipeline transport phases). However, the technique is also useful in mining and mineral processing, for petrochemical production, production of fertilizers, in power generation (hydropower, coal grinding, nuclear power, geothermal power), in the general chemical industry, cement industry, waste water treatment and food processing to mention some of the main areas.

Fig. 16 Illustration of a distillation column gamma scan to the left in the panel, the results in form of a density chart in the middle and the associated interpretation to the right in the panel.

Fig. 17 Typical scanning sectors for packed distillation columns – top view.

In this text, multiphase flow is defined as simultaneous movement of two or more of the following main constituents or phases in a confined space:

- Water (fresh or saline, continuous phase)
- Oil (or other organic water insoluble liquid components, continuous phase)
- Gas and gas mixtures
- Solid particles (sand, inorganic mineral scales or precipitations consisting of inorganic cations and organic anions. These particles may exhibit water-wetting or mixed wetting properties)
- Emulsions (oil in water or water in oil). These may be characterized as micro emulsions, which may be stable over extended time (i.e. coalescence rate is low) or emulsions which are generated and broken down continuously (i.e. coalescence rate is high).
- Asphaltenes and resins, which exhibit bipolarity but are mainly oil wetting.
- Gas hydrates, which are compounds of water and natural gas arranged in a more or less solid rigorous lattice.

In the petroleum industry, however, multiphase flow is often defined as the commingled flow of oil, water and gas only.

The need for multiphase flow measurement in the oil and gas industry has been evident for many years. Several such meters have been designed and developed since the early 1980s by research organizations, meter manufacturers, services supply industry, oil and gas production companies and others. They are designed to apply for large spans in the relative mass flow of the various phases. Flow structure varies with change in the superficial phase velocities³ of the individual components. This is illustrated for two-phase (water-gas) horizontal and vertical flow in Fig. 18A and B.

A simple clamp-on gamma transmission system for multiphase flow measurements is illustrated in Fig. 19. A collimated gamma ray beam (narrow beam) traverses the transportation tube with the internal flow and is detected with a gamma detector with spectroscopic properties, – typically a NaI(Tl) scintillation detector. It is also possible to use a wide-angle beam (broad beam) with a correspondingly collimated detector for a larger cross section view. Gamma attenuation takes place according to Eq. (2), but here slightly reformulated for two-phase flow, for instance oil and water:

$$I_{ow} = I_0 \cdot e^{-(\alpha_o \mu_o d + \alpha_w \mu_w d)} \quad (9)$$

Here, I_0 is the count rate recorded with empty tube, I_{ow} the count rate recorded with commingled oil and water flow, α_o and α_w the fractions of oil and water, respectively, μ_o and μ_w the effective linear attenuation coefficients of oil and water for the applied gamma energy, respectively and d the internal diameter of the tube. In addition, we have that:

$$\alpha_o + \alpha_w = 1 \quad (10)$$

By combining Eqs. (9), (10), the unknown fractions of oil and water, also called the hold-up fractions, α_o and α_w can be calculated.

Hence, for two-phase flow a source with only one gamma energy is sufficient, but the energy must be sensitive to phase ratios over a wide range. For instance, if gas is one of the fractions and may be the dominating one, a low-energy gamma like from ^{241}Am (60 keV) can be the best choice. With increasing mass thickness (g/cm^2), which is a function of both phase fractions and diameter

³Superficial phase velocity = the flow velocity in m/s of one phase of a multiphase flow, assuming that the phase occupies the whole conduit by itself. It may also be defined by the relationship (Phase volume flow rate)/(Pipe cross-section).

Fig. 18 Illustration of various flow structures in two-phase flow that dominate in certain areas of the map as a function of the superficial velocities of gas and water phases for a. horizontal and b. vertical flow. The figures are redrawn based on information in ref. [Corneliussen et al. \(2005\)](#).

Fig. 19 Clamp-on source-detector system for measurement of individual phase fractions in a vertical multiphase transport pipeline.

on the transportation tube, a higher energy gamma ray may be required. Either ^{133}Ba (main energy at 356 keV) or even ^{137}Cs (661 keV) may be a better choice.

For three-phase flow, say oil, water and gas, at least two different gamma energies are required ([Scheers and Slijkerman, 1996](#); [Khayat and Afarideh, 2019](#)). The gamma energies must be chosen so that their attenuation coefficients are sufficiently different. Again, ^{133}Ba is a viable choice because, in addition to its main energy at 365 keV, it has strong emissions at 80 keV and 303 keV as well. If a higher gamma energy is required, a mixed source of ^{133}Ba and ^{137}Cs is possible.

The formalism for three phases (o , w and g) and two gamma energies (1 and 2) is as follows:

$$I_{ow1} = I_0 \cdot e^{-(\alpha_o \mu_{o1} d + \alpha_w \mu_{w1} d + \alpha_g \mu_{g1} d)} \quad (11)$$

and

$$I_{ow2} = I_0 \cdot e^{-(\alpha_o \mu_{o2} d + \alpha_w \mu_{w2} d + \alpha_g \mu_{g2} d)} \quad (12)$$

I_{ow1} and I_{ow2} are measured for the two gamma energies and the values of all the effective linear attenuation coefficients and the diameter d of the tube are known (measured separately). But this time we have three unknowns and need three equations for solving α_o , α_w and α_g . The third equation is:

$$\alpha_o + \alpha_w + \alpha_g = 1 \quad (13)$$

By combining Eqs. (11)–(13), the individual hold-up fractions may be calculated.

If a 4th component, like for instance sand, is part of the mixture, 3 gamma energies are required and so on. It is very important to check regularly the values of the linear absorption coefficients that may change somewhat during operation due to change in oil composition or water salinity.

Gamma transmission and emission tomography

Gamma transmission tomography

Tomographic measurements of extended objects can be done with different methods (Wang, 2015), but here we concentrate on gamma transmission tomography. Gamma transmission tomography is a refinement of the simple fixed-geometry clamp-on single-beam gamma transmission setup. The same basic gamma attenuation principle applies here. Tomographic measurements allow not only hold-up fractions to be measured but also their spatial distributions over the cross section viewed by the source-detector arrangement (Johansen and Jackson, 2004; IAEA, 2008; Kim et al., 2011).

In tomographic imaging, multiple measurements are carried out at different directions through the object being investigated as illustrated in Fig. 20. The tomographic representation is generated by an image reconstruction technique where a 2D distribution of parameters, in this case mainly densities, is produced. Several sequential 2D images may also be stacked together to form a 3D image. Cross sections of spatial distribution of masses/phases under transport averaged over some preselected counting time are recorded. The time resolution is the counting time needed to achieve sufficient counting statistics in the measurements.

This technology can also be used to map the internal configuration of static objects that do not change constitution or composition within the time resolution window. Examples may be severe corrosion attack on pipeline internal walls or the precipitation of mineral scales or other deposits in the pipeline under inspection. Such information is used in the design and optimization of industrial processes and process equipment, and to improve accuracy of multiphase system measurements in general.

The technique is also useful in quite different areas such as revealing the hidden internal structure in cultural heritage objects or, for instance, detecting basal stem rot in living oil palms (Abdullah et al., 2013).

Tomographic equipment based on gamma transmission has undergone considerable development over time from the relatively simple 1st generation with movable source-detector setups with "pencil beam" scanning to the static version where there are no movable parts except from the tomography object itself. With reference to Fig. 20, a short description of each method is offered below.

1st generation: This is the simplest setup based on parallel scanning in which a source, emitting a single pencil beam of radiation, and a detector are coupled together so that the detector is always facing the source as illustrated in Fig. 20. The source and detector are moved linearly in increments to acquire individual measurement. After the completion of the linear measurement series across the object, both source and the detector are rotated to the next angular position to acquire the next set of measurements. Alternatively, the object itself can be rotated a preselected angle if it is not tied up to equipment above and below.

2nd generation: This setup is based on an array of detectors (8 detectors shown here) facing a single source. The source is collimated in such a way that the pattern of the beam is a fan with a thickness of about 5 to 10 mm. Although this is still a translation-

Fig. 20 Principles of different gamma tomography approaches from the simplest 1st generation setup to the most complicated with no movable parts. To some extent the figure also illustrates the developments which have taken place on a timeline. The figure is redrawn after information in ref. IAEA (2008).

rotation scanner, the number of rotation steps is reduced because the multiple pencil beams cover a larger area of the object in one single scan. Hence, the number of scanning angles can be reduced, and the scanning time considerably shortened.

3rd generation: This is perhaps the most popular scanner type. In this configuration, a larger number of detectors (here 18 individual detectors) are mounted in an arc concentric to the source. The size of the detector array is sufficiently large to cover the entire object in the detector field of view at all times. The relative position of the source and the detector remain stationary, while the entire apparatus rotates about the object. The data acquisition time is reduced relative to the two preceding scanners.

4th generation: This is a fixed detector-rotating source arrangement in which many detectors are mounted on a ring arrangement. The detector array forms a closed ring and remains stationary during the entire scan. The radiation fan beams sweep across the object while the source rotates continuously or stepwise in preset angle increments. One of the advantages of this scanner is less complicated mechanical setup, since the only moving component is the gamma source which, of course, is not wired, in contrast to moving wired detector arrays in the previous scanner versions.

5th generation: In fact, this is not a scanner in the sense that either source or detector or both move while scanning a pencil or a fan beam across the object. This version consists of several sources (5 sources in Fig. 20) positioned with equal spacing at a fixed distance from the scanning object. Each source emits a fan beam sufficiently broad to cover the whole diameter of the object. The transmitted radiation from each source is detected by a fixed array of individual detectors (12 detectors in Fig. 20) broad enough to cover the width of the fan beam. This setup can, in contrast to the previous 4, be used to scan objects with dynamic changes in nearly “true time” as demonstrated in ref. Johansen et al. (2014) (Fig. 21).

The type of tomographs described here can be applied for troubleshooting, for collecting information about internal structures of extended objects (beyond the range of traditional x-ray machines) and for monitoring dynamic processes in order to improve process modelling and optimization. However, each setup has its own limitations. Some of the limiting parameters or hardware requirements are tabulated in Table 2.

Gamma emission tomography

In gamma emission tomography there is no external radioactive source. The effective source here is a radioactive gamma-emitting component somehow distributed inside the object to be examined. The radioactive component can be a purposely located point source with isotropic gamma emission, a radioactive component more randomly distributed, or a fluid with a dissolved radioactive tracer compound. Outside the object, and in the simplest version, there is mounted a gamma detector that can be moved in a circular pattern around the object to detect radiation emitted from the source in different angles or the object itself can be rotated (Fig. 22). In more elaborate versions a ring of detectors is mounted around the object in a stable and regular pattern (Fig. 23). No scanning is needed for the generation of one slice tomogram. If the object is a vessel or tubing and the source is not a point source in fixed position, the ring of detectors may be moved axially to record new slice tomograms. In this way a 3D picture of the interior of the object may be generated.

One may distinguish between two somewhat different methods with acronyms SPECT and PET separately described below.

Fig. 21 5th generation gamma tomography system mounted on a transportation pipeline. Mind the removable gamma detector array that allows the scanner to be fitted around the pipeline. The pictured scanner is developed at the University of Bergen, Norway, by Johansen et al. (Johansen et al., 2014). The tomograph consists of 5 gamma sources of 18.5 GBq ^{241}Am (60 keV) each, and total of 85 CdZnTe semiconductor gamma detectors with 17 detectors in each of the 5 arrays. The tomogram slices shown to the right are extracted from a time series plot of a commingled oil and gas flow with data from one of the five detector arrays (17 detectors) of the high-speed gamma-ray tomograph. The time sequence is 2.5 s and the temporal resolution is 10 ms. The inner diameter of the pipe is 82 mm and the flow rates of the oil and gas are 100 and 50 cm/s, respectively. Courtesy of Prototech and University of Bergen.

Table 2 Approximate combinations of object sizes, needed gamma energies, suitable radionuclide sources and suitable tomography systems.

Object/vessel dimension	Approximate diameter/size	Needed gamma energies	Examples of radionuclides		Suitable for:
Small	< 150 mm	< 200 keV	x-rays, ^{241}Am (60 keV), ^{57}Co (122 keV)		All generations but special for 5th generation
Medium	150–600 mm	200–800 keV	^{133}Ba (356 keV), ^{137}Cs (661 keV)		All generations except 5th generation
Large	600–1500 mm	> 800 keV	^{59}Fe (1099 and 1292 keV)		Partly 1st and 2nd generation + 4th generation
Extra large	> 1500 mm	> 800 keV	^{60}Co (1174 and 1332 keV), ^{60}Co , ^{88}Y (1836 keV) and in special cases ^{56}Co (2598 keV)		4th generation but with narrow fan beam
Scanner Object	1st generation	2nd Generation	3rd generation	4th generation	5th generation
Static	Yes Rotation of object	Yes	Yes	Yes, Extended obj., narrower fan beam	Yes, but overkill
Dynamic (mass flow)	Very slow flow changes	Slow flow, time averaging	Slow flow, time averaging, Faster than 2nd	Slow flow, time averaging, Faster than 3rd	Yes, nearly true-time resolution.

**Fig. 22** Sketch of gamma emission tomography principle with radiolabelled internal volume, one detector and rotating object: Measurement of mineral scale distribution in a tubing section.

SPECT or Single Photon Emission Computed Tomography: This method utilizes radionuclides that emit one major gamma photon only. The optimal photon energy will vary according to the specific applications. In industrial setups where detector arrangements are as described above and for extended tomography objects, the energy may be relatively high (> 1 MeV), see Fig. 23. In research and development laboratories with smaller objects and where the detector consists of medical type gamma cameras (Anger cameras) with specially designed collimators, the photon energy must be much lower. The optimum energy is in the range of 140–150 keV, but some collimators can manage even 350 keV (Fig. 24). In addition to the shown parallel hole collimator, there are the converging hole collimator, the diverging hole collimator and the pinhole collimator, each with their own properties. An additional property to be considered for a SPECT-applicable radionuclide in industrial settings is its half-life. In contrast to the half-life of confined and encapsulated external sources used in gamma transmission tomography, which we want to be long (hundreds of days or rather years), the optimum half-life of SPECT-radionuclides are shorter, in the order of hours to a few days. These sources are distributed (and open) rather than confined and must be handled and taken care of after the experiment is finished. Short-lived radiotracers of this kind die away and leave no traces of radioactivity. Thus, radiological and environmental impact is strongly reduced.

Fig. 23 SPECT setup with 24 gamma detectors positioned in a ring outside a reaction barrel. For demonstration: A phantom insert with a gamma emitter generates tomograms like the one in the lower left corner (Courtesy of Korean Atomic Energy Research Institute KAERI).

Fig. 24 Sketch of the main components in a gamma camera (Anger camera). Operation is exemplified by recording a 2D activity distribution of a phantom object.

Anger cameras are not frequently used in industrial settings except from experiments in laboratory environment. Hence, the energy limitation posed by the Anger camera does not apply. On the contrary: For examination of extended objects, higher gamma energies are in many cases better, and tomography arrangements like that sketched in Fig. 23, developed in various versions, are preferred. Such arrangements are more flexible with respect to type and size of detector, detector collimation and operations.

Table 3 lists some useful SPECT-radionuclides as tracers or label on tracers for fluids of different kind and for solid particles in industrial settings.

The table proposes a selection only of various possible alternative radiolabels where the timing, size and type of the examination object dictate the needed nuclear properties. They may all be produced by nuclear reactions induced by thermal neutrons in a reactor.

PET or positron emission tomography

This method utilizes radionuclides that decay by emission of a positron which is a positively charged electron or an anti-electron. By travelling some short distance in the surrounding medium and upon hitting an orbital electron in a nearby atom, the positron

Table 3 Important nuclear data for radionuclides useful for SPECT examination of industrial processes.

Radionuclide	Half-life	Gamma energy (% intensity)	Applications in:
^{24}Na	15.0 h	1369 (100), 2754 (100) keV	Aq
^{38}Cl	37.2 m	2167 (44), 1642 (33) keV	Aq, Org

**Fig. 25** Principle sketch of a positron emission tomography system with detectors arranged in a ring around an object under examination.

combines with electron and both masses disappear under emission of two photons, both with energy of 511 keV, which is the equivalent energy of the mass of an electron. The two photons, which are generated simultaneously, are emitted with angle of (approximately) 180° with respect to each other (Fig. 25). This coincident and directional (relative to each other) photon emission is the basis for the technology called positron emission tomography or PET. Since around the mid-1980s it has found wide application in the medical sector, and most modern hospitals with radiological competence have implemented this technology. The development has been somewhat slower in industries not related to the medical sector.

The imaging principle is that the positron annihilation must be found somewhere on the straight line between the two detectors that have registered the two photons in coincidence. When many such events have been recorded between detectors in the detector ring, finally a "density" plot will appear where detector tie-lines are crossing each other most frequently. This represents a 2D map, tomogram, of activity distribution in this cross section. A 3D picture can be generated by moving the detector ring axially in increments or moving the object across the detector ring.

In recent PET developments, detector setups have become more and more sophisticated. Some types of instrumentation now use detector blocks which are combinations of several small detectors in a 2D array. This allows the possibility of recording not only a narrow 2D slice of the object for each position, but a 3D image over a defined volume. An additional important development is the introduction of time-of-flight, TOF, of the photons. In traditional PET technology, only photons coincident within a defined

time window and the corresponding detector position are recorded. In the new development, the *time differences* of the two photons are also recorded. With reference to Fig. 25, the time it takes for one photon to travel from the site of annihilation, say t_1 to detector D1, and the time it takes, t_2 , for the corresponding photon to reach detector D2, can now be recorded even though the photons travel with the speed of light. Thus, one can infer where on the tie-line between the two detectors the annihilation has taken place. This aids in improving the sharpness of the spatial resolution.

There is, however, one important physical factor in PET that is impossible to ignore and circumvent, and that affects the spatial resolution of this technology. Positrons are emitted from the radioactive nucleus with a certain kinetic energy. The energy depends on the specific radioactive nucleus. Therefore, the positron travels some distance in matter depending on the mass density, or rather on the electron density. The annihilation does not take place until the positron is near the end of its path. Thus, and in practice, the annihilation takes place at a position different from that of the nucleus that emitted the positron. This leads to blurring of the true position. However, modern picture reconstruction algorithms have come a long way to improve or compensate for this “built-in” physical limitation.

Some positron emitters, conditionally applicable in various industrial settings, are tabulated in Table 4. They may all be produced in simple proton- or neutron-induced nuclear reactions at small cyclotrons or in reactors, except from ^{82}Sr which requires somewhat higher bombarding energy.

Regarding detectors, some of the earlier technical applications of PET technology used position-sensitive wire grid chambers originally developed for high-energy physics. One such application was the examination of lubrication efficiency of Rolls Royce motors where the oil was labelled with a positron emitter (Stewart et al., 1988).

In practice, PET systems range from the very simple setups with two detectors only to the most complex pet scanners with hundreds of detector crystals systems most often based on solid scintillators. Originally, NaI(Tl)-detectors were dominating, and plastics based on organic scintillators like stilbene and anthracene were also in use. Today, a range of new detector crystals have been developed and implemented with improved overall properties for PET-applications.

The following is a brief listing of such detector scintillation crystals, some of them doped with cerium: Barium fluoride (BaF_2), bismuth germanate (BGO, $\text{Bi}_4(\text{GeO}_4)_3$), gadolinium orthosilicate (GSO, $\text{Gd}_2(\text{SiO}_4)\text{O}:(\text{Ce})$), lutetium-yttrium orthosilicate (LYSO, $\text{Lu}_{1.8}\text{Y}_2(\text{SiO}_4)_4\text{O}:(\text{Ce})$), lanthanum bromide ($\text{LaBr}_3:(\text{Ce})$), lutetium fine silicate (LFS, unknown (proprietary) chemical composition), lutetium aluminate (LuAP , $\text{LuAlO}_3:(\text{Ce})$), lutetium iodide ($\text{LuI}_3:(\text{Ce})$) and lutetium orthosilicate (LSO: $\text{Lu}_2(\text{SiO}_4)\text{O}:(\text{Ce})$). In addition, the semiconductor CZT ($\text{Cd}_{0.9}\text{Zn}_{0.1}\text{Te}$) is used. Detector technology is continuously improving.

A few industry-related applications

There are numerous applications of gamma emission and transmission tomography published in the literature. Here, a few examples are selected for illustration purposes.

Healthy or infected tree stems?

Detection of the oil palm stem rot diseases is a major issue in estate management and production in oil palm plantations. In order to avoid costly and time-consuming conventional manual diagnostic techniques based on chemical analysis of root stem tissue, an alternative method based on gamma transmission tomography has been developed (Abdullah et al., 2013). It consists of a transportable equipment that can readily be applied on living trees in plantations (see Fig. 26). This system produces high quality tomographic images that clearly differentiate between healthy and infected oil palm stems as shown in the inset in the upper left corner of Fig. 26. This method offers a promising alternative for in situ inspection of oil palm stem diseases compared to the more conventional methods, which, in extreme cases, include cutting down the trees.

Table 4 Selection of radionuclides with important nuclear parameters conditionally applicable for PET imaging of static objects and dynamic processes.

Radionuclide (nucl. react.)	Half-life	Positron energy (% intensity), ($E_{\beta\text{max}}$) (keV)	Gamma energy	Applications in ^a :
^{18}F	109.7 m	634 (97)	No γ	Aq-C, Org

Fig. 27 Principle sketch of a scanning system for non-destructive assay of solid drummed radioactive waste from nuclear power plants. The system accommodates two scanning modes: Gamma transmission using an external radioactive source and gamma emission measuring on the gamma radiation from radioactive waste in the drum (Venkataraman et al., 2005).

Activity distribution in nuclear waste - combined transmission and emission tomography

An integrated system that combines gamma transmission and emission tomography was developed for the non-destructive assay of solid drummed radioactive waste from nuclear power plants (Venkataraman et al., 2005). The system is intended for assaying waste items up to 320 l with a contact dose rates up to a maximum of 2 Gy/h. A principle sketch of the scanning system is given in Fig. 27.

The scanning system is equipped with an adjustable aperture collimator on the detector side, and the distance of the detector from the drum can also be varied. The distance is chosen based on the measured dose rate of the item, and a selection of lead attenuators with different thickness may be applied to reduce count rate to reasonable levels.

The matrix density distribution is measured by monitoring transmitted gamma radiation from a source of ¹⁵²Eu with an activity of 0.55 GBq. ¹⁵²Eu has gamma emission with energies ranging from 122–1408 keV. It is a well-suited radionuclide for transmission experiments when used together with a detector with high energy resolution like the semiconductor HpGe (high-purity germanium).

In addition to the gamma transmission mode, the drum can also be scanned to map radioactivity distribution and hot spots by detecting the gamma radiation emitted from the drum itself, i.e. in the gamma emission mode. This is the main objective of the equipment. The object is scanned in 3-degrees of freedom; rotation, translation and elevation.

The derived density distribution is then used to correct gamma attenuation from the radiation emitted by the radioactive content in the drum. The system is not designed for a very high spatial resolution of the density or the radioactivity distribution, but rather for a high output. Resolution of approximately 50 mm voxel size is obtained, which is suitable for the purpose.

Fig. 28 Simple PET setup with two opposing detectors mounted on a 2D (semi 3D) scanner for detection of profiles of fluid flow during core-flooding in porous media Courtesy of Dr. A. Haugan, IFE, Norway.

Front instability when displacing oil with water - monitored with PET

In most oil reservoirs, water is injected in injection wells to displace oil from the reservoir rock and drive the oil forward to production wells. This is termed secondary oil production. However, if the viscosity of the water is considerably lower than that of the oil, the displacement front becomes unstable and so-called fingering develops. This results in a less efficient sweep of the reservoir and, thereby, lowers oil production. A considerable amount of movable oil is left untouched in the reservoir. One of the remedies is to increase the viscosity of water by injecting slugs of a water-soluble polymer in order to stabilize the displacement front (see also [Thereska, 2021](#)). This method belongs to the suite of so-called enhanced or tertiary recovery methods. During the development of improved oil recovery methods, it is important to increase the understanding of the mechanism and structure of fluid flow in

porous media like the reservoir rocks. Extensive laboratory experiments have been performed and are still being executed where such fluid flow and oil displacement mechanisms are studied. In this work, gamma (and X-ray) transmission and emission methods are attractive, and in some cases the only viable examination alternatives. X-ray transmission and gamma emission using SPECT and PET are in active use. While X-ray transmission cannot effectively be used if the density contrast between the fluids is absent or low, SPECT and PET are not sensitive to density contrasts. However, X-ray tomography (CT) is excellent to map permeability contrasts in the porous medium itself.

Fig. 28 shows a simple setup (“poor man’s PET”) with two NaI(Tl)-detectors that can be turned around the examination object and the object can be turned between the detectors. The object in this case is an encapsulated sandstone core saturated with oil. Brine labelled with the positron emitter $^{22}\text{Na}^+$ displaces the oil, and fingering develops. The flow is stopped at time intervals for recording of PET images.

Fig. 28C shows a recorded tomogram with developed brine fingers. Thus, brine properties and heterogeneities of the core plug may be modified to examine the effect on the brine front stability.

More sophisticated PET core-flooding experiments have been published using multi-modality systems where medical PET scanners have been combined with CT (Fernø et al., 2015; Brattekkås et al., 2020; Hu et al., 2020).

Studies like the ones described here generate data for a fundamental understanding of fluid flow in porous media and, thereby, for mathematical model development of these processes. Such models, which are developed on the pore-core scale, are again the basis for upscaling attempts and, thereby, for full-scale reservoir simulation models. Work continues along these lines.

Glossary

Barn A unit for reaction probability of a nuclear reaction, also called reaction cross section. $1 \text{ b} = 1 \text{ b} \equiv 10^{-24} \text{ cm}^2$ (or 10^{-28} m^2).

Bremsstrahlung Electromagnetic radiation (also sometimes called X-rays) generated by charged particles (normally electrons) when accelerated (or bent) in an electromagnetic field. This “type” of X-rays has a continuous energy distribution without definite structure, with energies stretching from eV to several tens of MeV, depending on the kinetic energy of the accelerated particle.

Excitation function A graphical representation (plot) of the reaction cross section as a function of the energy of the bombarding particle.

Gas proportional counter This is a type of gaseous ionization detector device used to measure particles of ionizing radiation including neutrons. The two most well-known are the ^3He -filled detector, based on detection via the nuclear reaction $n + ^3\text{He} \rightarrow ^3\text{H} + p$, and the BF_3 -filled detector, based on the nuclear reaction $n + ^{10}\text{B} \rightarrow ^7\text{Li} + \alpha$. The emitted charged particles (p and α) give rise to an electrical pulse that is amplified and detected. The Intensity of the pulse is proportional to the energy of the incoming neutron.

LIPAC Linear prototype accelerator—an initiative in a Japanese/European program called IFMIF (International Fusion Materials Irradiation Facility) to provide an accelerator-based, D-Li neutron source to produce high energy and intensity neutrons for fusion research. The initiative includes building a prototype accelerator with a 9 MeV deuteron beam with intensity of 125 mA.

MCP Microchannel plate, a detector concept for cold, thermal and epithermal neutrons consisting of a micro-perforated (microchannels) glass plate where the glass matrix contains nuclides with high neutron capture cross sections like ${}^6\text{Li}$, ${}^{10}\text{B}$ or ${}^{155,157}\text{Gd}$. Nuclear reactions induce emission of charged particles, which upon recoiling out of the matrix cross the micro-perforations and kick out an avalanche of electrons from the tube walls. These electrons are accelerated and multiplied in an electrical field and exit the plate with a measurable intensity. This detector is position sensitive with very high spatial resolution.

NAA Neutron activation analysis, a sensitive analytical technique for qualitative and quantitative analysis of chemical elements in nearly any type of matrix. It is based on irradiation of the sample with neutrons (various energies), thereby generating radioactive nuclides in the sample, followed by detection of the emitted radiation, which is element (and isotope) specific like a fingerprint.

PGNAA Prompt gamma neutron activation analysis, an analytical technique for qualitative and quantitative non-destructive analysis of chemical elements in nearly any type of matrix. It is based on irradiation of the sample with neutrons (various energies are possible), inducing nuclear reactions like absorption or scattering, thereby exciting the nuclei to higher energy levels followed by spontaneous and fast de-excitation by emission of gamma rays. Detection of the intensity and energy of this radiation uniquely defines the chemical element (even the isotope of this element) and its concentration.

Scintillation detector A detector principle for ionizing radiation consisting of the two concepts solid scintillation and liquid scintillation. A solid scintillator is a (mono) crystal or another solid material (doped plastics) which, upon hitting by gammas, neutrons or charged particles, generates isotropic emission of photons, which may be detected by a photomultiplier and further amplified into a measurable current pulse. A liquid scintillator works with the same principle, but is based on a liquid solution of the scintillating compounds.

Semiconductor detector This is a detector for nuclear radiation based on the semiconductor principle. When applied for neutron detection, typically a planar thermal neutron conversion layer consisting of a thin film of neutron reactive material is deposited on the surface of a semiconductor diode. ${}^{10}\text{B}$ and ${}^6\text{LiF}$ are frequently used as conversion layer materials. The reaction product particles emitted in the neutron-induced nuclear reactions with ${}^{10}\text{B}$ (α -particles) and ${}^6\text{Li}$ (α - and ${}^3\text{H}$ -particles) will create electron-hole pairs in the semiconductor material which will travel to the positive, respectively to the negative, pole in an electric field set up over the semiconductor thus creating a current pulse. The number of electron-hole pairs is proportional to the energy of the radiation to the semiconductor.

SONATE This is an on-going French initiative to develop an accelerator-based neutron source with sufficiently high neutron flux for neutron scattering investigations, thus replacing nuclear reactors for this purpose. This design is referred to as "SONATE." It is based on acceleration of a high-current proton beam to energies < 50 MeV impinging a lithium or beryllium target.

Introduction

A neutron is a non-charged sub-atomic particle with masses slightly greater than that of a proton. Together with positively charged protons, neutrons are bound with the strong nuclear force in atomic nuclei. In this state, neutrons are of no use for material testing. However, neutrons can also exist, one by one, outside the nucleus in a free state. In this form, the neutron has a half-life of ~ 10.2 min. It decays into a proton, an electron and an antineutrino according to the equation

$$n^0 \rightarrow p^+ + e^- + \bar{\nu}_e$$

The neutron has an internal structure (Garcia, 2021a) consisting of quarks (one up-quark and two down-quarks) as shown in Fig. 1. That is the reason why the neutron should no longer be categorized as an elementary particle as was common years ago, and

Fig. 1 Quark structure of the neutron: u = up-quark, d = down-quark. Neutron decay leads to formation of two up-quarks and one down-quark.

which can still be found in technical texts from qualified laboratories. This internal structure has, however, no relevance to the practical use of neutrons, and will therefore not be explained further here.

Since the neutron has no electric charge, it is not affected and cannot be accelerated in electric fields. However, the neutron has a magnetic moment and can, therefore, be influenced by magnetic fields. This interaction, together with other properties like scattering, allows slow neutrons to be guided from its source of production to an experiment several meters away (see also Garcia, 2021a; Dewji and Miller, 2021).

Neutrons with high energies (so-called fast neutrons) can be produced in various nuclear reactions, for instance with charged particles as the bombarding beam. The resulting neutron may then be slowed down (moderated) to energies lower than that resulting from the nuclear reaction. At these slow, cold and ultra-cold energies, the neutron shows a strong interaction with several chemical elements, quite in contrast to interactions with gamma rays.

These special properties make neutron interactions and gamma interactions with matter complementary methods for examination of materials. This complementarity is utilized in numerous practical applications since the two irradiation forms are influenced by different properties of an examination object.

Neutron interactions with matter

Fig. 2 systematizes the various nuclear interactions that a neutron can have with matter, i.e. with atomic nuclei. Fig. 3 schematically visualizes some of the reaction types mentioned in Fig. 2.

Scattering reactions

This term includes elastic scattering (n, n) and inelastic scattering (n, n'). In elastic scattering a fast neutron imparts a fraction of its kinetic energy to the target nucleus without transferring excitation energy to that nucleus. If the neutron is thermal, that is, in thermal equilibrium with the medium nuclei, there is no net energy transfer between the neutron and the nuclei. In inelastic scattering a fast incoming neutron is scattered away with a lower energy than it had upon arrival. The difference is given to the nucleus as excitation energy which can be followed by emission of gamma radiation. Very low energy neutrons can also undergo diffraction like waves (Wietfeldt, 2021). This very specialized area is covered in (Barradas, 2021; Wietfeldt, 2021). In general, the different forms of scattering reactions utilize neutrons with energies from super-cold to fast (see classification below). Each isotope of the various chemical elements has its unique probabilities for such interactions. We call this probability (microscopic) cross section. The unit is *barn* (b), and it has the dimension of area ($1 \text{ b} = 10^{-28} \text{ m}^2$ or 10^{-24} cm^2 which is more frequently used in formulas) denoted in Fig. 2 by σ_e for elastic scattering and σ_i for inelastic scattering. Cross sections for each type of nucleus depend on the neutron energy. The energy dependence curve is called the *excitation function*. The parameter Σ in Fig. 2 is explained in the text below.

Absorption reactions

This term describes two mechanisms: (1) compound nucleus formation without fission and (2) compound nucleus formation followed by fission. Common for the two is that the nucleus absorbs a neutron. The probability for this event is generally highest at low

Fig. 2 The figure intends to show the various types of reactions that neutrons induce when interacting with atomic nuclei. The main reactions of relevance for material testing are the scattering, absorption and transfer reactions. Other reactions like neutron-induced spallation and fragmentation reactions can only take place with high-energy neutrons ($E_n > 100 \text{ MeV}$) and are, therefore, of no interest as direct probes in this text. However, proton-induced spallation installations are modern large-scale tools to provide high fluxes of spallation neutrons for a number of material investigations. Some of the features in the figure is explained in the text.

Fig. 3 Schematic illustration of some neutron reactions with nuclei. The mechanisms include neutron scattering, absorption (compound nucleus formation) with emission of prompt gamma rays, transfer reactions where charged particles, neutrons and gamma rays are promptly emitted and fission of certain heavy nuclei where additional neutrons and gamma rays are emitted.

and thermal energies. The process leaves the nucleus in a highly excited state corresponding to the binding energy of the neutron in the nucleus (5–8 MeV).

Let us first consider the reaction without fission. Most of the time the nucleus gets rid of the excitation energy by emitting an avalanche of gamma rays, more seldom particles and, “finally,” after some picoseconds, ends up in the ground state (**Fig. 4**). A new isotope of the bombarded element has been formed. Here, there are two features to be noted: (1) the energies and intensities of the prompt gamma rays are unique for the formed isotope and (2) the new isotope may (or may not) be radioactive ([Previtali, 2021](#)). Upon decay it may emit gamma rays where energies and intensities are also unique for the decaying radionuclide. We say that this gamma ray pattern is the “fingerprint” of the radionuclide. These properties are the basis for *prompt gamma neutron activation analysis* (PGNAA) and ordinary *neutron activation analysis* (NAA). Such processes add to the extensive suite of nuclear methods for material examination since they describe qualitatively and quantitatively the isotopic content, and thereby also the elemental content for elements that can be considered to have the natural isotopic composition.

For heavy nuclei such as ^{233}U , ^{235}U , ^{239}Pu , absorption of a thermal neutron makes the resulting nucleus so unstable that it tends to break up into two pieces, one fragment somewhat lighter than the other. The fission is accompanied by emission of 2–3 new neutrons per event. This process is the basis for running nuclear reactors, where the surplus of neutrons is used both in activation and scattering experiments. If high-energy neutrons are available as bombarding particle, several other heavy nuclei may undergo fission. Examples are ^{232}Th and ^{238}U .

Again, these processes are governed by microscopic cross sections, here called σ_c and σ_f .

Fig. 4 Illustration of the neutron capture process forming a compound nucleus, which decays to its ground state by emission of prompt gamma rays.

Transfer reactions

These reactions are most relevant for neutrons with energies in the range of several MeV. The neutron transfers parts of its kinetic energy to neutrons and protons in the bombarded (target) nucleus. This energy may exceed the neutron or proton separation energies (binding energies) in the nucleus. The particles are emitted from the nucleus, and new nuclei are formed. Alpha particles may also be emitted in this process as illustrated in Figs. 3 and 5. Each of the reactions has a probability expressed by a cross section value for each individual nuclide. In Fig. 2 this is denoted as σ_x , which is the sum of all individual microscopic transfer reaction cross sections ($\sigma_{n,p}$, $\sigma_{n,\alpha}$, $\sigma_{n,2n}$, etc.). The individual probabilities differ in magnitude, i.e. some reactions proceed more readily than others. The probability for a certain reaction channel may be compared with a barrel of water with outlet channels of different sizes. The water outflow is directly proportional to the size of the opening. Thus, with reference to Fig. 5, the highest cross section for this special nuclide is for the (n,2n)-reaction.

Neutron overall interactions relevant for transmission experiments

It is possible to ascribe a total microscopic cross section, denoted σ_t in Fig. 2, for a chemical element by combining all the individual isotopic cross sections and multiplying it with the fraction that each individual isotope contributes to the chemical element, which we call the isotopic abundance. We define the total macroscopic cross section Σ_t as:

$$\Sigma_t = \sigma_t \cdot N \quad (1)$$

Here, N is the atomic density (atoms/cm³) of the chemical element. Strictly speaking, Σ is not a cross section since it has the dimension cm⁻¹, but it can be used as an attenuation coefficient for neutron transmission through matter. Thus, neutron transmission through a material slab consisting of only one single chemical element is, as for transmission of gamma radiation (see Bjørnstad, 2021a,b), simply described by Lambert-Beer's law

$$I_d = I_0 \cdot e^{(-\Sigma_t \cdot d)} \quad (2)$$

where d = average penetration length in cm. If the material slab consists of more chemical elements, say 3, homogeneously mixed, with macroscopic cross sections Σ_{t1} , Σ_{t2} and Σ_{t3} and individual penetration lengths d_1 , d_2 and d_3 , the expression becomes

$$I_d = I_0 \cdot e^{(-[\Sigma_{t1} \cdot d_1 + \Sigma_{t2} \cdot d_2 + \Sigma_{t3} \cdot d_3])} \quad (3)$$

By introducing the number of atoms per unit volume of element $i = N_i$, the effective transmission length or path of element $i = d_i$, the energy-dependent total microscopic cross section for the isotope j of element $i = \sigma_{ij}(E)$ and the isotopic abundance of isotope j of element $i = A_{ij}$, the detailed final expression becomes

$$I_t(E) = I_{t0}(E) \cdot e^{\left(-\sum_i N_i \cdot d_i \cdot \sum_j \sigma_{ij}(E) \cdot A_{ij}\right)} \quad (4)$$

Σ_i and Σ_j in the exponent of Eq. (4) are not the macroscopic cross sections but the symbols for summation.

Neutron energy classification

Neutron energies can span the range from super-cold to very high (> 10 MeV) energies. Still, classification of neutron energies into selected "energy bins" seems to be useful. The reason is that neutrons with energies within defined ranges show different interactions

Fig. 5 Illustration of the neutron transfer reactions with emissions of protons, neutrons, alpha particles and prompt gamma rays before the resulting nuclide ends up as an isotope of a chemical element different from that of the target element.

with material. There is, however, no strict and unified agreement in the literature or in the nuclear community on how to classify. In the text below, one such classification is proposed.

Ultra-cold neutrons—Below 0.001 eV

The production, transportation and storage of ultra-cold neutrons (UCN) is currently motivated by their usefulness as a tool to determine properties of the neutron itself and to study various fundamental physical interactions. Such fundamental interactions will not be discussed in this text since they have no clear practical relevance for material examination. It can be mentioned that UCNs have been used to measure the presently accepted half-life of neutrons of ~ 10.2 min.

Cold neutrons

Neutrons of energies between 0.001 and 0.01 eV are termed cold neutrons and are used in several types of scattering (diffraction) applications such as studies on the structure of biological molecules and particulate objects in the nanometer range. Absorption reactions can also occur at these energies with high cross sections (see example of ^{238}U in Fig. 6). This is of value both for transmission experiments, for increased production of selected radionuclides, and for analytical purposes (NAA and PGNA).

Thermal neutrons

Neutrons that are in thermal equilibrium with the motion of the atoms of a medium at room temperature (20°C) are called thermal neutrons. Their energy is described by a Maxwell-Boltzmann distribution that has a maximum value at 0.0253 eV. In nuclear reactors with higher moderator and cooling medium temperature, this maximum shifts to higher values. Thermal neutrons are used in neutron diffraction studies of material molecular structures, in neutron scattering and radiography for mechanical structures and in activation analysis of elemental compositions of materials.

Epithermal neutrons

Epithermal neutrons have energies between thermal (0.025 eV) and a few hundred eV. The epithermal region is characterized by strong oscillations in the excitation function for most nuclei. These oscillations are related to the internal structure (excited states) of the bombarded nucleus: At some defined energies the probability of absorbing a neutron (n, γ) becomes high, corresponding to populating definite excited states. There are also fission and scattering resonances. As the neutron energy increases, the density of the oscillations increases because the spacing of excited states decreases. For some nuclei, especially among the lanthanide elements, these oscillations are very strong. Hence, in conventional neutron activation analysis of elemental contents of materials, one often prefers epithermal rather than thermal neutrons. Neutrons in this energy region can be separated from thermal neutrons by absorbing the thermal neutrons in a cadmium foil, which has a very large capture cross section for thermal neutrons and is relatively transparent for epithermal neutrons. Other reactions like elastic and inelastic scattering also take place in this energy range.

Fig. 6 Cross section for (n, γ)-reaction of ^{238}U as function of incoming neutron energy. Curves like this are called excitation functions for the actual nuclear reactions, here for the (n, γ)-reaction. The figure also defines approximate regions for ultra-cold, cold, thermal, epithermal, slow and fast neutrons.

Slow neutrons

Slow neutrons have energies between hundreds of eV to 0.5 or 1 MeV. This energy range overlaps into the resonance region and strong neutron absorption can take place. However, it is not the most useful energy region for material testing, although both elastic and inelastic scattering take place, which can be used in neutron radiography and tomography.

Fast neutrons

Generally, fast neutrons have energies between 0.5 and 10–20 MeV. This is the energy region where transfer reactions start to be possible. (n,p)- and (n, α)-reactions dominate for nuclei with $Z < \sim 40$. For most nuclei there is a threshold energy below which transfer reactions cannot take place. This is because the outgoing charged particle must penetrate the coulomb barrier set up by the nuclear charge. Threshold energies for different elements vary in the approximate region 2–12 MeV. There are a few examples of (n,p)- and (n, α)-reactions which, in fact, are exothermic, i.e. there is no energy threshold for the neutron. One such example is the formation of ^{14}C from ^{14}N by the reaction $^{14}\text{N}(\text{n,p})^{14}\text{C}$. Two examples for (n, α) reactions are $^6\text{Li}(\text{n},\alpha)^3\text{H}$ and $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$, where there are no lower limits for the neutron energy; their thermal cross sections are exceptionally high, i.e. 940 b and 3840 b, respectively. (n,2n) reactions are dominant for elements with $Z > \sim 40$. The threshold energies start at higher values than those for the previously mentioned reactions because sufficient energy must be transferred to overcome the neutron binding energy in the nucleus. These reactions are of interest in nuclear activation analysis of elemental compositions of materials. Such neutron energies are also used in fast-neutron transmission radiography and tomography experiments.

High energy neutrons

High-energy neutrons have energies above 20 MeV and are found in cosmic radiation, where energies as high as 1000 MeV has been measured. In the laboratory, high-energy neutrons can be produced in high-energy spallation reactions. An example is the high-energy neutron facility at Los Alamos Lab (Nowicki et al., 2017). In Spallation reactions with 800 MeV protons on tungsten, they obtain a neutron flux in the energy range 10–600 MeV of $2 \cdot 10^6 \text{ n/cm}^2 \cdot \text{s}$, where it seems that about 25% have $E_n > 100 \text{ MeV}$. This neutron flux is $3.5 \cdot 10^8$ times larger than the cosmic neutron flux at sea level. These fluxes make possible dose effect experiments of high-energy neutrons on biological systems. Such neutrons may also be used for testing of the survival of electronic components to be used in space missions. For ordinary and routine material examinations, however, such high-energy neutrons have no obvious use at present.

Neutron sources

This sub-chapter provides a brief description of the main sources for free neutrons to be used in various forms of material testing (see also Wehe, 2021; Miller et al., 2021; Garcia, 2021b).

Isotopic neutron sources

The simplest neutron producing devices are the isotopic (and isotropic) neutron sources. Three main types of such neutron sources can be distinguished. One type is based on alpha-emitters, usually mixed with beryllium metal, which produce neutrons through the (α ,n)-reaction. The second is based on high-energy gamma-emitters, usually mixed with deuterium or beryllium producing neutrons through the (γ , n)-reaction. The third is simply selected isotopes of heavy elements (actinides) that undergo spontaneous fission with emission of $\sim 3 \text{ n/f}$, where ^{252}Cf is the most prominent example. The reason why beryllium (^9Be) and deuterium are chosen is that these are the two radionuclides with the lowest neutron separation energies at 1667 and 2220 keV, respectively. Extensive overviews of such sources are found in Hoste (1988) and Knoll (2010).

Table 1 lists some possible isotopic neutron sources containing beryllium and provides also some information about a gamma-based source and a source based on spontaneous fission.

Neutrons can be generated in α -reactions with target material nuclides other than ^9Be , but with substantially lower yields. Here follow some examples, in brackets is the neutron yield in % of the yield from a beryllium target: ^7Li (3.3%), ^{10}B (16.3%), ^{11}B (32.5%), ^{13}C (12.5%), ^{18}O (36.3%) and ^{19}F (15.0%). Thus, the only practical target material for α -induced neutron production is beryllium.

For all aspects considered, the source based on $^{241}\text{Am}/\text{Be}$ stands out as the most versatile and general-purpose isotopic neutron source.

The neutron-producing reaction is as follows:

The source strength (n/s) is proportional to the activity of ^{241}Am . Sources with more than 50 Ci (1850 GBq)¹ have been produced. Sources in use in industry are typically in the range 50 mCi (1.85 GBq) to 10 Ci (370 GBq), smaller for hand-carried

¹1 Ci (Curie) = $3.7 \cdot 10^{10}$ disintegrations per second (dps) = $3.7 \cdot 10^{10}$ Bq (Becquerel, 1 Bq $\equiv$ 1 dps).

Table 1 Some isotopic neutron sources with selected nuclear data, average neutron energy and neutron yields.

Neutron source	Half-life	α -Energy (intensity) (MeV ^a)	Average neutron energy (MeV)	Neutron yield n/s·Ci (n/s·GBq)
²¹⁰ Po/Be	138 days	5.30 (100%)	4.2	$2.5 \cdot 10^6$ ($6.8 \cdot 10^4$)
²²⁶ Ra/Be	1600 years	4.78 (93.8%)	3.9	$1.5 \cdot 10^7$ ($4.1 \cdot 10^5$)
²²⁷ Ac/ ²²⁷ Th/Be	21.8 years	$5.76 + 5.97 + 6.06$ (68.1%)	3.8	$1.5 \cdot 10^7$ ($4.1 \cdot 10^5$)
²³⁸ Pu/Be	87.7 years	5.50 (70.9%)	4.0	$2.8 \cdot 10^6$ ($7.6 \cdot 10^4$)
²³⁹ Pu/Be	24,110 years	5.16 (70.8%)	4.6	$1.6 \cdot 10^6$ ($4.3 \cdot 10^4$)
²⁴¹ Am/Be	432.6 years	5.49 (84.8%)	4.5	$2.2 \cdot 10^6$ ($6.0 \cdot 10^4$)
²⁴⁴ Cm/Be	18.1 years	5.80 (76.9%)	4.3	$3.0 \cdot 10^6$ ($8.1 \cdot 10^4$)
¹²⁴ Sb/Be	60.4 days	Gamma: 1691 (47.6%)	0.02	$1.9 \cdot 10^5$ ($5.1 \cdot 10^3$)
²⁵² Cf	2.65 years	Spontaneous fission	1.0	$2.34 \cdot 10^6/\mu\text{g}$ ($6.3 \cdot 10^4$)

^aIntensity of the strongest α -energy.

Fig. 7 Energy spectrum of neutrons from a ²⁴¹Am/Be isotopic neutron source reproduced from information in Marsh et al. (1995). Example of such a source is shown in the inset. For comparison, a neutron energy spectrum from a ²⁵²Cf fission neutron source is shown (red). Reproduced from Hassan AM (2001) Uses of isotopic neutron sources in elemental analysis applications. In: 3rd Conference on Nuclear & Particle Physics (NUPPAC 01), Cairo, Egypt, 20–24 October. Available from <https://www.osti.gov/etdweb/servlets/purl/20808702>.

devices. The physical size of the source can be tailormade to the various application but is generally small as indicated in Fig. 7. It is encapsulated in a double stainless-steel housing. Neutron energies vary from nearly thermal to about 11 MeV with an average around 4.5 MeV (Fig. 7). In the neutron-producing nuclear reaction a prompt gamma energy of 4.44 MeV is emitted from an excited state in ¹²C. The dose rate from an unshielded source, which is relevant in the human handling process, has been measured to 0.68 $\mu\text{Sv/h}^2$ at 1 m/GBq.

Table 1 also contains some information for the gamma-based ¹²⁴Sb/Be source. Other high-energy gamma emitting radionuclides may be used like ²⁴Na ($E_\gamma = 2754$ keV, used both with beryllium and deuterium) and ⁸⁸Y ($E_\gamma = 1836$ keV, used with beryllium). Both are challenged with some impracticalities. The first one can be produced in a nuclear reactor in sizable amounts but is too short-lived ($T_{1/2} = 15$ h). The second one ($T_{1/2} = 106.6$ days) must be produced by charged particle irradiation in a cyclotron or a linear accelerator with particle currents limited to the microampere (maximum 1 mA) region and with relatively small reaction cross sections.

The best among these is the ¹²⁴Sb/Be source. The radioactive ¹²⁴Sb-source is placed in a cavity in the beryllium block. When the activity becomes too low due to radioactive decay, it can in principle be removed, reactivated in a nuclear reactor and mounted back into the beryllium block. However, all isotopic neutron sources based on a high-energy gamma emitter are impractical in transportable devices due to the need for heavy shielding against gamma radiation.

The ²⁵²Cf source is more versatile. It is used both in industry (for instance well logging in the petroleum industry) and in permanent laboratory installations. The physical size of the source is comparable to the one for ²⁴¹Am/Be. The neutron yield per GBq or per μg is comparable to that of ²⁴¹Am/Be, but very strong sources can be made especially for laboratory (activation) use. The energy

²Absorbed dose is measured in Gray (Gy) where $1 \text{ Gy} \equiv 1 \text{ J/kg}$. The effect of this dose in humans (equivalent dose) is measured in Sievert (Sv) where $1 \text{ Sv} \equiv 1 \text{ Gy} \cdot \text{WR}$ where WR = radiation weighting factor which expresses the harmfulness of the actual radiation type (different for β , α , γ , neutrons, etc.).

spread is narrower towards lower energies than for the $^{241}\text{Am}/\text{Be}$ source (Fig. 7), and this reduces the needed thickness for a moderator to produce epithermal or thermal neutrons.

Sealed-tube neutron generators

Neutrons can also be produced by fusion of light hydrogen nuclei like deuterium and tritium. This may sound complicated and perhaps require large laboratory installations, but modern development has made it straight forward. Comprehensive overview texts are found in IAEA (2012), Valkovic (2015) and Chichester (2009). The following text concentrates around the use of so-called sealed tube neutron generators. These are small accelerators enclosed in sealed glass tubes. Depending on the generator design, one or more of three different fusion reactions $\text{D} + \text{T}$, $\text{D} + \text{D}$ or $\text{T} + \text{T}$ may take place. The working principle is illustrated in Fig. 8 and exemplified with a $\text{D} + \text{T}$ reaction. The tube contains a reservoir of deuterium bound as hydride in a thin and finely powdered metal layer (for instance in titanium as TiD_x where $x_{\text{max}} = 2$) on a molybdenum backing. Upon heating, some of the deuterium is released to a few (2–4) millitorr and ionized in an ion source, mainly to produce D_2^+ . In some generators, and depending on the type of ion source, D^+ is the dominating species. One type of ion source used is the Penning type (electron bombardment), another source is based on radiofrequency ion generation (RF-source).

A negative potential (typically 150 kV) accelerates the positively charged ions against a target containing tritium, for instance as TiT_x ($x_{\text{max}} = 2$). A nuclear fusion reaction takes place between deuterium and tritium resulting in production of a neutron according to the reaction

or

The 17.59 MeV is the total reaction energy divided as kinetic energy between the neutron and the α -particle.

The neutrons are nearly monoenergetic with energies in the range 14–15 MeV (Figs. 9 and 10).

With a deuterium-loaded target the reaction becomes

These neutrons are also close to monoenergetic with energy of 2.45 MeV (Fig. 9).

For thin targets the neutron energy also varies with the angles in which neutrons are emitted relative to the incoming deuterium particle and with the applied accelerating voltage. This is illustrated in Fig. 11. For the D–D reaction the neutron energy is approximately 2.45 MeV at 90 degree angle, while for the D–T reaction the neutron energy is around 14.1 MeV for the same angle.

The D–T reaction has the largest maximum cross-section of 5.0 b ($5 \cdot 10^{-24} \text{ cm}^2$) of all fusion reactions. Maximum cross-section of this reaction is reached at an acceleration potential of only 64 keV. At 100 keV acceleration voltage the cross sections are 3.43 b and 0.033 b for the D–T and D–D reactions, respectively. The cross section varies as a function of acceleration voltage (Fig. 12).

Neutrons produced from the D–T reaction are emitted isotropically from the target in the mass middle point system. Neutron emission from the D–D reaction is slightly peaked in the forward (along the axis of the ion beam) direction. In both cases, the He nucleus (^4He and ^3He , respectively) is emitted in the exact opposite direction of the neutron. This is a very interesting fact as it can be

Fig. 8 Principle sketch of a sealed-tube neutron generator. Here, deuterium ions are accelerated against a target consisting of tritium bound as hydride in a metal (here TiT_x), and the resulting neutron flux distribution.

Fig. 9 Approximate energy distribution for the DT, DD and TT reactions that take place in a sealed-tube neutron generator.

Fig. 10 Measured high-resolution energy distribution for produced neutrons from the DT-reaction. Redrawn from information in Rigamonti D, et al. (2018) *Measurement Science and Technology* 29.

utilized to perform space-resolved (tomographic) pictures of the neutron interaction with extended external objects (see Bjørnstad, 2021b).

In modern neutron generators the gas that is ionized and accelerated is a mixture of deuterium and tritium. The cross section for the T-T fusion reaction

is much lower than that for the D-T reaction, but similar in size to the D-D reaction (only 3.4×10^{-2} b at an acceleration voltage of 100 keV). The main purpose of the tritium gas is, therefore, to replenish used tritium in the target due to reactions, evaporation and sputtering. Because of this, some T-T reactions take place. Since two neutrons are emitted per reaction, the energy spectrum is not “monoenergetic” but shows a broader energy distribution as shown in Fig. 9, since the reaction energy now must be shared among three particles.

Sealed-tube neutron generators based on reactions described above come in different sizes, shapes and with different neutron output (n/s) from the smallest of ~ 200 n/s (“neutrons on a chip”) (Elizondo-Decanini et al., 2012) to more than 10^{13} n/s (Phoenix, 2020). They are all relatively small instrumentation. The footprint of the largest generators is 5–15 m² exclusive external shielding. These are mainly meant for permanent installation in a laboratory. However, the latest years have seen a vivid development of small-size generators that are transportable and even portable with neutron outputs in the range 10^6 – 10^9 n/s. In addition, those

which are based on the D-D reaction do not contain any radioactive material (in contrast to the D-T generator). This makes handling, logistics and transport easier, even across country borders. Thus, they can be implemented directly in the industry and civil engineering for resolving various operational challenges. A few examples are shown later. A typical portable generator is shown in Fig. 13. The weight of this one is only 15 kg.

Neutron generation based on small-to-medium size accelerators

Apart from sealed-tube neutron generators, three other types of accelerator-based neutron-producing devices are the electrostatic accelerators, the cyclotrons, and the linear accelerators (García, 2021b).

Fig. 13 Example of a portable sealed-tube neutron generator for use in industrial and civil service settings. Courtesy of Thermo Fisher.

Radiofrequency quadrupole (RFQ) linear accelerators (Schempp, 2000) or drift-tube Linacs (Wrangler, 2008) or a combination of the two are potentially a very good solution to the delivery of large proton (or deuteron) beam currents at energies of a few MeV. At present, neutron generating equipment based on the compact linear accelerator design can produce from 10^8 to more than 10^{13} n/s by bombardment of beryllium targets (Fig. 14). R&D and engineering work is now going on to develop linear accelerators with a proton current in the range 10–100 mA. Proton energies of 30 MeV can be obtained over an acceleration distance of 25–30 m.

One of the ongoing initiatives is the development of the SONATE project at CEA in France (Ott et al., 2020) with protons on a beryllium target. What is the achievable neutron yield? Although the melting point of beryllium is relatively high (1287 °C), the limit for power-dumping of a proton beam into a stationary target is probably ~ 100 kW. This means that there is a trade-off between the beam current (mA), the proton energy (MeV), and the duty cycle (%) of the pulsed beam. For example, for a proton energy of $E_p = 20$ MeV, a peak current of 100 mA and a 4% duty cycle, the power on the target would be 80 kW and the neutron yield would be 3.1×10^{14} n/s. If the proton energy is increased by a factor 2 to 40 MeV, while the power on the target remains limited at 80 kW, the duty cycle must be reduced to 2% and the neutron yield is 5.4×10^{14} n/s. For a given power deposited on the target, the neutron yield is roughly proportional to the proton energy. This neutron output is a factor of more than 10–50 compared to the highest yields achievable from state-of-the-art sealed-tube neutron generators.

Another modest-size linear accelerator, LIPAC (Cara et al., 2016), is at present being developed in a European-Japanese collaboration. It accelerates deuterons to 9 MeV with a peak current of 125 mA. This accelerator is mainly being developed for fusion research, but, obviously, it has potential as a general-purpose high-intensity neutron source as well.

Such neutron-generating equipment exhibits long lifetimes at full output, as there is little target or beam degradation. Since they do not use radioactive materials, licensing requirements are less stringent than for isotopic sources or tritium sealed-tube generators. These pulsed systems based on the RFQ accelerator are well suited for applications requiring a high peak neutron flux, including activation analysis of very short-lived reaction products and various forms of laboratory-based neutron imaging and scattering experiments.

Cyclotrons (Fig. 15) can also be used as a source of protons to generate neutrons from a target of lithium or beryllium. However, the obtainable proton flux for a state-of-the-art small and medium-size cyclotron with maximum energies in the range 18–30 MeV is considerably less than for the Linacs mentioned above. A small hospital-type cyclotron (for PET radionuclide production) with

Fig. 14 Principle sketch of radiofrequency-based linear proton accelerator producing neutrons from a beryllium target.

Fig. 15 Principle sketch of a small-to-medium size cyclotron accelerating protons against a neutron-producing target of beryllium.

$E_{\text{max}} = 18 \text{ MeV}$ provides a maximum proton output of $300 \mu\text{A}$ (IBA Cyclone[®] KIUBE³). A larger version, which provides an energy in the range 15–30 MeV, offers a maximum proton current of 1.5 mA (Cyclone[®] 30⁴).

Reactor neutrons from fission

Most research reactors today are conventionally based on fission of ^{235}U with isotopic enrichment in the range 4–20% and light or heavy water as the moderator and cooling medium. Obtainable neutron flux in the core of research reactors is in the range 10^{12} to $> 10^{15} \text{ n/cm}^2 \cdot \text{s}$ (Fig. 16). Research reactors provide many options for exposing target materials to high neutron flux and for extracting neutron beams for a variety of material property studies (O’Kelly, 2021).

Neutrons from bremsstrahlung reactions

This neutron source is based on the interaction of high-energy photons with the atomic nucleus. Then, where do the high-energy photons come from?

Photons are produced when high-energy charged particles, for instance electrons, imping on and are decelerated in material. The high-energy electrons are produced in electron accelerators. Two mechanisms are active. The first is that an incoming electron interacts with an orbital electron around a nucleus, kicks the orbital electron out of the atom leaving an electron “hole,” which subsequently is filled with electron transition from an outer electronic shell. This process is illustrated in Fig. 17 showing the removal of an electron from the K-shell. The resulting hole in the K-shell is filled by electron transition from the L-shell. The hole in the L-shell is

Fig. 17 Production of elementary X-rays and bremsstrahlung when high-energy electrons interact with orbital electrons in an atom or with the electromagnetic field of the nucleus.

subsequently filled from the M-shell and so on. Roughly speaking, one can say that the energy difference between the L- and the K-shells is emitted in the form of an element-characteristic X-ray, in this case a K-X-ray. Energy of elemental X-rays are generally below 100 keV (uranium and thorium has slightly higher energies), and these energies are too low for neutron production.

The other mechanism is that the incoming electron interacts with the electromagnetic field of the nucleus, resulting in deceleration of the speed and bending of its trajectory. The difference in electron energy before and after the bending is emitted as photons generally known as *breaking radiation* or *bremstrahlung*. This process gives rise to a continuous photon energy spectrum from its energy maximum close to the energy of the incoming electron down to very low energies. The intensity of the photons (photon flux or luminosity) increases towards lower energies. Increasing energy of the incoming electron results in shifting the photon energy spectrum towards higher energies. Thus, photon energies can be high enough to overstep the neutron binding energy in nuclei.

The high-energy photons impinge on a target typically of a high-Z element like tantalum or tungsten and interact with the nucleus of the elements. These photonuclear interactions, also known as the nuclear photo effect, are interactions where a photon disturbs the internal co-ordination of the nucleus. When the photons have energies above the typical binding energy range of the nuclei ($> 5\text{--}10$ MeV), these interactions generally lead to the emission of nucleons—both neutrons and protons. However, for heavy element targets like tantalum and tungsten, the emission of protons is suppressed due to the Coulomb barrier. The nucleon emission is mainly due to the four processes of giant nuclear dipole resonance, quasi-deuteron production, delta resonance, and vector meson dominance (Pisharody et al., 1998). Only the first process is of importance for photon energies in the 10–30 MeV range, and the various mechanisms will not be further discussed here.

When the same high-Z material is used both in the photon production and in the neutron generation, the whole process can take place simultaneously within the same physical target. For the higher photon energies, photo-fission (Methasiri and Johansson, 1971) may also be a component in this process leading to emission of fission neutrons as well (Fig. 18). Resulting neutron energies depend on the photon energy distribution and the neutron separation energy of the target element. Generally, the energy spectrum stretches from a few MeV down to low energies.

Neutrons from spallation reactions

At proton energies of 100 MeV and slightly higher, spallation reactions begin to take place, and at 1 GeV and higher, spallation is the dominating nuclear reaction process (Fig. 19). The process starts with a high-energy incoming proton hitting a target atom of a heavy element like lead, tantalum, tungsten, mercury or even thorium or uranium. The high-energy proton transfers kinetic energy to protons and neutrons in the nucleus. The result is that some of these sub-atomic particles are promptly knocked out of the nucleus leaving the rest-nucleus (in Fig. 19 called the excited nucleus) in an excited state. This part of the spallation process is called the intra-nuclear cascade. The rest-nucleus disposes off its remaining excitation energy by different mechanisms. One mechanism is the further evaporation of mainly neutrons and cascades of gamma rays until the excitation energy has reached a level below the neutron separation energy. Another mechanism is that the excited nucleus has sufficiently high energy to fission, leading to emission of fission neutrons and subsequently of delayed neutrons during beta-decay of the radioactive fission products. A third

Fig. 18 High-energy electron induced generation of high-energy photons and the photon interaction with high-Z nuclei to produce neutrons directly and through an associated photo-fission process.

Fig. 19 Principle sketch of the spallation process leading to production of a shower of neutrons over a broad energy range.

mechanism is alpha, beta and gamma emission, leading to a nucleus (in Fig. 19 called the spallation residue), which has an atomic number (Z) a few units below the target nucleus. The new Z-value depends on the number of protons knocked out in the intra-nuclear cascade and on eventual alpha particle emissions until the spallation residue nucleus is reached. Thus, a number of neutrons over a broad energy spectrum are produced in the spallation process.

Facilities based on spallation sources provide the most intense pulsed neutron beams for scientific research and industrial development, and several facilities have been built through the years. One of the largest is the SNS⁵ at Oak Ridge in United States. A new European initiative is the ESS⁶ presently being built in Lund in Sweden where user programs are scheduled to begin in 2023.

Neutron detectors

There are three main categories of general-purpose neutron detectors (Han, 2021):

- *Gas proportional counters* use a gas to amplify the charge from the original charged particles generated by a neutron absorption reaction in the conversion material.
- *Scintillation detectors* use solid or liquid scintillating materials that emit light when struck by an incoming neutron.
- *Semiconductor detectors* consist of semiconductor chips where the charged particles emitted in the neutron absorption reaction deposit energy creating an electric signal.

In addition:

- *Microchannel plates (MCP)* has been in use in past years for the detection of, for example, X-rays and electrons. Development of this principle for position sensitive neutron detection in scattering and tomography experiments has taken place over the last 20 years.

Each of these principles, which are essential in any neutron transmission and scattering applications, are briefly described below. Additional material on neutron detectors can be found in Han (2020).

Gas proportional neutron counters

Gas proportional counters have been used for many years for the detection of nuclear radiation. Proportional counters operate at relatively high voltages of up to about 2000 V and with proper filling gases they can multiply the original ionization without introducing nonlinearities to obtain reasonable pulse sizes of several volts. When they include a filling gas of the correct composition, they can be used for neutron detection (Fig. 20).

Traditionally, these proportional counters were filled with BF₃, which provides good detection efficiency for thermal neutrons. These detectors exploit the high reaction cross section for ¹⁰B (3840 b) for thermal neutrons in the reaction:

Fig. 20 Principle sketch of a gas proportional counter, which also can be used for detection of thermal neutrons if the filling gas contains BF₃ or ³He.

⁵<https://neutrons.ornl.gov/sns>

⁶<https://europeanspallationsource.se>

The discovery that ^3He provided better overall neutron detection capability, also for neutrons with higher energies, resulted in the almost unanimous use of this as the filling gas for proportional counters in neutron detection. Proportional counters with other filling gases can also be used by depositing solid forms of B or Li inside the proportional counters (Knoll, 2010).

When ^3He is the active material in the filling gas, the following nuclear reaction takes place (cross section for thermal neutrons is 5330 b):

The produced proton creates an electrical signal by ionizing the filling gas molecules.

In the later years, the commercial availability of ^3He has been decreasing due to the huge demand for neutron detectors in border control and similar applications. One may say that ^3He has become a “strategic material” with limited free trade. This commercial shortage of ^3He , paired with high increase in prices, has caused a return to the use of BF_3 gas or the use of scintillation detectors for the detection of neutrons.

Solid scintillation neutron detectors

Scintillation neutron detectors include liquid organic scintillators, solid crystals, plastics, glass and scintillation fibers.

Neutron-sensitive scintillating glass fiber detectors

The scintillating glass fibers work by incorporating ^6Li and Ce into a glass bulk composition. The doped glass is extruded into fibers. The ^6Li has a high cross-section for thermal neutron absorption (940 b) through the reaction:

The alpha particle and triton interact with the glass matrix to produce ionization, which transfers energy to and excite the Ce-atoms. Upon deexcitation, a portion of the emitted scintillation light propagates through the glass fiber, which also acts as a light-guide (Fig. 21). The ends of the fiber are optically coupled to a photomultiplier tubes (PMTs) to detect photon bursts. The event results in a flash of light of several thousand photons for each neutron absorbed.

The scintillating fiber detectors have excellent sensitivity, they are rugged, and have fast timing ($\sim 60 \text{ ns}$) so that a large dynamic range in counting rates is possible. The detectors have the advantage that they can be formed into any desired shape and can be made very large or very small for use in a variety of applications. Further, they do not rely on any raw material that has limited availability, nor do they contain toxic or regulated materials. Their performance matches or exceeds that of ^3He -tubes for gross neutron counting due to the higher density of neutron absorbing species in the solid glass compared to high-pressure gaseous ^3He . Even though the thermal neutron cross section of ^6Li is lower compared to ^3He (940 b vs. 5330 b), the atom density of ^6Li in the fiber is 50 times greater. This results in an advantage in effective neutron capture probability ratio of approximately 10:1.

Crystalline neutron scintillation detector

LiCaAlF_6 is a neutron sensitive inorganic scintillator crystal, which like neutron-sensitive scintillating glass fiber detectors makes use of neutron capture by ^6Li . Unlike scintillating glass fiber detectors, however, the ^6Li is part of the crystalline structure of the scintillator, giving it a naturally high ^6Li density. A doping agent is added to provide the crystal with its scintillating properties. Two common doping agents are cerium (Ce) and europium (Eu). Europium doped LiCaAlF_6 has the advantage over other materials in that the number of optical photons produced per neutron capture is around 30,000–40,000, depending on the level of

Fig. 21 Working principle of a scintillation fiber detector for thermal neutrons where the fiber has been doped with ^6Li .

Eu-dopant (0.5–2 mol%). This is more than five times higher than for example in neutron-sensitive scintillating glass fibers (~ 6000 photons/n).

Due to its high ${}^6\text{Li}$ density, this material is suitable for producing light weight compact neutron detectors. The long decay time of Eu-doped LiCaAlF_6 ($\sim 1.6 \mu\text{s}$) makes it less suitable for measurements in high radiation environments. The cerium-doped variant has a shorter decay time ($\sim 40 \text{ ns}$) but suffers from a somewhat lower light-yield (~ 4000 – 5000 photons/n).

Semiconductor neutron detectors

Solid state semiconductors represent one of the basic important detection principles for neutron measurement. When compared with gas-filled detectors, they have the potential to be more compact, operate at lower voltages, and be more robust against vibration-induced noise.

A typical planar thermal neutron conversion layer detector consists of a thin film of neutron reactive material deposited on the surface of a semiconductor diode. ${}^{10}\text{B}$ and ${}^6\text{LiF}$ are frequently used as conversion layer materials because of their stability, large thermal neutron absorption cross-sections, and primary reaction products.

The functional principle is sketched in Fig. 22 for the case of ${}^6\text{Li}$. In the case of ${}^{10}\text{B}$, the most common primary reaction products generated by neutron absorption are alpha particles (1.47 MeV) and ${}^7\text{Li}$ ions (840 keV). When a nuclear reaction occurs in the ${}^{10}\text{B}$ conversion layer, these charged particles will travel into the semiconductor material where they can create electron-hole (e-h) pairs.

A critical design parameter for planar conversion layer devices, which is ultimately responsible for limiting the maximum thermal neutron detection efficiency, is the thickness of the conversion layer material. The probability that a neutron will be absorbed in the conversion layer increases with increasing layer thickness. For ${}^{10}\text{B}$, $\sim 90\%$ of incident thermal neutron flux will be absorbed in a $\sim 50 \mu\text{m}$ thick layer, for ${}^6\text{Li}$ somewhat less. If the conversion layer is too thick, the reaction products may be absorbed before reaching the semiconductor. The average travel range in ${}^6\text{LiF}$ for the 2.05 MeV alpha particle from ${}^6\text{Li}$ -reactions is $6.3 \mu\text{m}$, while the range for the corresponding triton (T) is $34.7 \mu\text{m}$. Average travel ranges for the 1.47 MeV alpha particle and 840 keV ${}^7\text{Li}$ ion in ${}^{10}\text{B}$ are 3.9 and $1.7 \mu\text{m}$, respectively. Conversion layer thicknesses for planar conversion layer devices are limited by the average travel ranges of the reaction products. Detector efficiency may be improved by a detector configuration like the one in Fig. 23.

This design has been improved several times (McGregor et al., 2010; Engelmann and Martin, 2011; Bellinger et al., 2014), and development is continuously on-going to achieve higher energy resolution and sensitivity than other room temperature detectors currently available. The new detectors integrate one or more relatively thin films incorporating a neutron-sensitive element, such as gadolinium, boron, or lithium, with semiconductor detector materials. The configuration is a stacked multilayer diode design that allows for use of a wide variety of materials. The electrodes can be made of conventional metallic materials such as copper or chromium, and the semiconductor detector layers can be made of silicon, germanium, or gallium arsenide. For all possible forms, the design is easily adapted to well-established semiconductor manufacturing techniques.

Microchannel plate detectors (MCPs)

Microchannel plates are currently being applied for high-resolution neutron counting with spatial resolution as small as $\sim 20 \mu\text{m}$ and temporal resolution in the order of $\sim 1 \mu\text{s}$ (Tremis et al., 2008).

Fig. 22 Sketch of the working principle of a semiconductor detector for thermal neutrons where a thin layer doped with ${}^6\text{Li}$ reacts with the neutron to produce an α -particle and tritium, both ionizing a semiconductor material which, for instance, may be silicon (Si). A current pulse is produced and transmitted to read-out electronics.

Fig. 23 Principle of a semiconductor detector with a multilayer structure for better detector efficiency. Layers are not to scale since the layer of LiF is only a few μm thick while that of silicon can be 40–50 μm .

MCPs upon inspection look like a thin glass disk perforated with microscopic holes. They typically consist of several million microchannels or capillaries fused together into a monolithic disk-like structure (a section of which is shown in Fig. 24). Each capillary is an independent, microscopic channel electron multiplier (Fig. 24).

The glass is doped with a neutron-absorbing material, typically either ${}^6\text{Li}$ or ${}^{10}\text{B}$. Upon reaction with an incoming thermal or epithermal neutron, the emitted alpha and triton particles penetrate the thin glass walls and enter into the evacuated capillaries where they hit the capillary wall (mostly two times). Electrons are kicked out from an electron-donating material on the wall surface of the capillaries. These electrons are accelerated in a potential put across the microchannel plate, hitting the wall several times—kicking out new electrons etc. An avalanche of electrons exits the channels with a current sufficiently large to be registered by backing electron-detecting devices. MCPs are able to amplify extremely weak signals by 10^3 – 10^7 , yielding output signals that can be easily handled by auxiliary electronic equipment.

Fig. 24 Expanded view and cut of a microchannel plate detector where the thin glass matrix is doped with the neutron-absorbing nucleus ${}^{10}\text{B}$. Reaction products recoiling out of the glass into the evacuated microchannels induce an avalanche of electrons that are accelerated in an electric potential put across the plate and electrons exit the structure in the bottom. Here, the electrons are registered by auxiliary electronic equipment.

The microchannels are usually of a circular or square geometry with 6–12.5 μm wide pores with 7.2–15 μm center-to-center spacing. The thickness of the disk is typically 40–250 times larger than the pore diameter (the L/D or aspect ratio), resulting in typical wafer thicknesses of only 0.4–1 mm. MCPs can be fabricated with an active area $\geq 10 \times 10 \text{ cm}^2$.

Although the glass mixture can contain only a limited proportion of neutron-absorbing atoms, this deficiency is compensated in MCP collimators by the possibility to produce structures with very large aspect ratios. The ratio of pore length to its width LMCP/d for current technology can be as high as 250:1.

These detectors have several areas of use, but especially within the neutron scattering, radiography and tomography examinations since they provide position-sensitive properties with spatial resolution in the 20–50 μm range.

Glossary

CFD Computational fluid dynamics,—a branch of fluid mechanics that makes use of different mathematical algorithms and numerical analysis in order to analyze and solve problems involving fluid flows. It is based on the Navier-Stokes equations that describe how the velocity, pressure, temperature, and density of a moving fluid are related. Practical applications include analysis of air flow for an aerodynamic aircraft design, analysis of the hydrodynamic properties of a boat hull, industrial design of oil and water piping, and processing equipment like multiphase separators, and many more.

CNL Compensated neutron log,—a well logging tool for the determination of matrix porosity. The tool contains a strong neutron source and two detectors situated 15 in. and 25 in. from the source. The tool is designed to be sensitive to thermal neutrons and is, therefore, negatively affected by any chlorine content. The critical measurement for this tool is the *difference* in the thermal neutron population as registered by the two spaced detectors, which results from neutron capture and neutron scattering.

Cross section Each isotope of the various chemical elements has its unique probabilities for defined types of nuclear interactions like scattering, absorption, or transfer reactions. We call this probability the (microscopic) cross section. The unit is *barn* (b), and it has the dimension of area ($1 \text{ b} = 10^{-28} \text{ m}^2$ or 10^{-24} cm^2 , which is more frequently used in formulas). The symbol used is the Greek letter σ . The cross sections for each type of nucleus depend on the neutron energy. The energy dependence curve is called the *excitation function*. See also (Bjørnstad, 2021b).

GNT Gamma Ray/Neutron Tool,—a well logging tool for the determination of matrix porosity. It contains a neutron source and a single detector that is sensitive to high energy capture gamma rays and thermal neutrons. The measurement principle is that rock pores filled with hydrogen-containing liquids (water or oil) will thermalize and capture the neutrons. The degree of thermalization is a function of H-content and, thereby, the porosity. In addition, it detects high-energy capture gamma rays from thermal neutron capture in H, O, and C. Unfortunately, it is sensitive to the concentration of chlorine in the formation brine and other well fluids because chlorine has a relatively high cross section for capture of thermal neutrons, thereby overestimating the porosity.

Imbibition The process of absorbing a wetting phase, in this case water, into a porous rock is termed imbibition. Imbibition is important in petroleum production where reservoirs are under water injection (secondary oil recovery) and the reservoir rock is water-wetting. Spontaneous imbibition requires no external force: water intrudes and oil is expelled out of the rock pores.

NAA Neutron activation analysis,—a sensitive analytical technique for qualitative and quantitative analysis of chemical elements in nearly any type of matrix. It is based on irradiation of the sample with neutrons (various energies), thereby generating radioactive nuclides in the sample, followed by detection of the emitted radiation that is element (and isotope) specific like a fingerprint.

NCT Neutron-induced computed tomography,—a neutron imaging technique for revealing structure and elemental contents of extended objects by rotating the sample in the beam of neutrons and recording multiple 2D images through an angular range of 180 degrees with position-sensitive neutron detectors. From the data set, a 3D representation through the object (tomogram) can be constructed.

Neutron imaging The principle of neutron imaging is based on the attenuation, through both scattering and absorption, of a directional neutron beam by an object through which it passes. Since different materials vary in their ability to attenuate neutrons, both composition and structure can then be probed. Both NR and NCT are neutron imaging techniques.

NORM Naturally occurring radioactive material,—material found in the environment that contains long-lived radioactive elements of natural origin. Examples are uranium (mainly ^{235}U and ^{238}U), thorium (^{232}Th) and potassium (^{40}K) and any of their decay products such as radium (mainly ^{226}Ra and ^{228}Ra), radon (mainly ^{222}Rn) and lead (^{210}Pb). The material may exist in “natural concentrations” like in tailings from uranium or thorium mining or as a product of human or industrial activity where the concentrations have been physically or chemically enhanced like in radioactive scale from the petroleum production industry.

NR Neutron radiography,—a neutron imaging technique for revealing structure and elemental contents of extended objects. It involves placing an object in the path of the neutron beam and measuring the shadow image (projection) of the object with a position-sensitive neutron detector.

Penetration depth In the present text, the term *penetration depth* is taken to mean how deeply in mm a beam of thermal neutrons (here at 27 °C) penetrates a particular chemical element in its solid or liquid form before the intensity of the beam has been reduced by a factor $1/e$, i.e., to about 37% of its original intensity.

PGNAA Prompt gamma neutron activation analysis,—an analytical technique for qualitative and quantitative non-destructive analysis of chemical elements in nearly any type of matrix. It is based on irradiation of the sample with neutrons (various energies are possible), inducing nuclear reactions like absorption or scattering, thereby exciting the nuclei to higher energy levels followed by spontaneous and fast de-excitation by emission of gamma rays. Detection of the intensity and energy of this radiation uniquely defines the chemical element (even the isotope of this element) and its concentration.

RPM Rotations per minute,—describes the rotation speed for an object under angular rotation.

Saturation In this context, saturations is taken to mean water saturation. This is the fraction of the pore space in the reservoir rock occupied by water (denoted S_w). In a petroleum reservoir, two other phases may co-exist with water; namely, oil (with saturation S_o) and gas (with saturation S_g). We then have that $S_w + S_o + S_g = 100\%$ (of the available porosity). In a typical native oil reservoir S_w may range from 10% to 50%, and is 100% in a pure aquifer.

SNP Sidewall neutron porosity tool,—a well logging tool for the determination of matrix porosity designed for use in open holes only. The tool has a neutron source and a single neutron detector with a 16 in. spacing. The detector is sensitive to *epithermal* neutrons. These neutrons are not yet slow enough to take part in absorption reactions with hydrogen and chlorine. Hence, the SNP tool readings are unaffected by the presence of chlorine in high salinity muds and formation fluids.

TOF Time-of-flight,—the measurement of the time taken by an object, particle or wave (for instance a neutron, a charged particle or an electromagnetic photon quantum) to travel a distance through a medium, in many cases through vacuum.

Water-wetting This is the ability of a water to spread over a surface of reservoir rock, resulting from intermolecular interactions when the two are brought in contact. The degree of wetting is termed wettability. A water-wettable surface may also be termed hydrophilic and a non-wettable surface hydrophobic. One method for measurement of water wettability is the contact angle of a drop of water placed onto the surface. The contact angle is the angle at which the liquid-vapor interface meets the solid-liquid interface. A completely water-wetting surface has a contact angle of 0 degrees, i.e., the water spreads uniformly and covers the complete surface. Most oil reservoir rocks have a so-called intermediate wettability.

XCT X-ray computed tomography,—a nondestructive technique for visualizing interior structures within solid objects, and for obtaining digital information on their 3-D geometries and properties. The measurement principle is based on the attenuation of the X-rays, which mainly depends on density (including electron density).

Introduction

This chapter should be read back-to-back with (Bjørnstad, 2021b), which sketches the technical background for practical neutron applications. Portions of the material in this chapter are also covered in (Thereska and Brisset, 2021a,b).

Neutron interactions are used in many different scientific fields. The methods are all based on some form of scattering or diffraction or on absorption. Data like those plotted in Fig. 1 are fundamental for some of the applications. Neutron methods can be used to study a wide range of object sizes from macro-sizes to nano-particle sizes and molecular level sizes. Neutrons can penetrate and

Fig. 1 Synopsis of the thermal neutron penetration depth (yellow points) and the thermal neutron absorption cross section (green points) for all chemical elements from H to U. A high absorption cross section is most often paired with a low penetration length. Data for penetration depth are redrawn from information in (Pynn, 1990) and corresponds to thermal neutrons at 27 °C.

probe into solid bulk material and reveal hidden structures, elemental compositions, and/or malfunctions and assist in testing the tolerance limits of crucial engineering components.

This chapter does not, however, discuss in detail studies on the nano or molecular level with neutron diffraction techniques (single crystal structure determination, powder diffraction studies, small angle neutron scattering (SANS) etc.). The examples of use given in the following text are all relating to the studies of macro-objects. Likewise, a major analytical technique like the beta-delayed neutron activation analysis, NAA, is not treated in any detail here. Several educational texts exist already in the published literature on this technology, see for example (Bode, 2017; Amiel, 2012; De Soete et al., 1972; Alfassi, 1990).

Neutron backscatter (or back-diffusion)

Soil water content

Knowledge about soil water content is important in agriculture (irrigation strategy) and in construction work of roads and buildings for ground compaction work. Water content may differ greatly from surface coverage where the water is “held” so strongly by the soil particles that it is not available to plants. When a soil is at this minimum “available” water content, it is said to be at the “wilting point.” On the other hand, there is a maximum concentration that can be maintained without the water draining rapidly. This is called the “field capacity.” Representative values for some soil types are given in Table 1.

It seems appropriate to define the soil water content as the volume of water per volume of soil (V_w/V_s). However, this will not be a perfect definition because different soils may swell or shrink with varying water saturation, but it is applicable within limits. A measurement method for water content should be able to handle the whole range of water saturation.

Various soil moisture measurement methods have been developed including heat capacity, electrical conductivity and electromagnetic pulse travelling time approaches. All have their own strengths and weaknesses, but these will not be discussed here. Below, we will exclusively refer to the neutron back-scattering (or back-diffusion) method.

This method uses the principle of neutron thermalization. Hydrogen nuclei are most effective in slowing neutrons down towards thermal energies due to similarity in mass (Wietfeldt, 2021). Thermalization time in water is of the order of a few μ s.

Table 1 Water content at minimum and maximum for a few soil types (IAEA, 2008).

Soil type	Wilting point (V_w/V_s in %)	Field capacity (V_w/V_s in %)
Coarse sand	2	6
Fine sand	4	10
Loamy sand	6	14
Loam	12	27
Clay	25	40

When the neutron has reached thermal energy, it runs the risk of being captured by any of the atoms in the close-by surrounding media. This risk depends on a combination of the absorption cross sections of the elements in the solid phase and the liquid phase and their respective abundances. For briny waters, chloride (Cl^-) may be one of the main neutron-capturing elements. For the solid particles, iron (Fe) may be abundant and one of the important neutron-capturing elements.

A few of the neutrons emitted from the neutron source bounce back, and even fewer of these backscattered neutrons have at this stage reached thermal energies without having been captured in compound nucleus formation of the surrounded media. These thermal neutrons will be registered by the detector, which is exclusively sensitive to thermal neutrons (BF_3 - or ^3He -counters).

The most frequently used isotopic neutron source for this instrument is the $^{241}\text{Am}/\text{Be}$ source with an energy spectrum, as shown in Fig. 7 of (Bjørnstad, 2021b), and an average energy about 5 MeV. The source strength or the neutron output is typically $\sim 10^5$ n/s corresponding to a ^{241}Am -activity of ~ 1.5 GBq (~ 40 mCi).

Fig. 2 displays the principle of a portable equipment for near-surface humidity measurement mostly used during road construction and soil compaction work and of construction material. The neutron source is lowered down from its shielded position to the surface of the object to be measured, for instance the soil. Emitted neutrons penetrate some 10–30 cm into the ground. Exact depth depends on water saturation. For 80% of the returned thermal neutrons, the penetration depth can be estimated by the empirical expression $\text{Depth (in mm)} = 280 - 2.7 F$ where F = fraction of water in % as defined above (<https://www.troxlerlabs.com>). For 10% water content (realistic for loamy sand, Table 1) this penetration depth amounts to ~ 25 cm. Some of the thermalized neutrons diffuse back towards the surface and are detected by the neutron detectors in the instrument.

In agriculture, another configuration of the same measurement principle has been developed shown in Fig. 3. This consists of a surface electronic equipment also housing a shielded neutron source with associated detectors for thermal neutrons. An access tube (made of aluminum) must be installed into the ground down to the depths of measurement interest. The source/detector arrangement is lowered on a wireline into the access tube and readings on thermalized back-diffused neutrons are recorded as a function of depth.

The detector reading is a function of the water saturation and the type of soil. Therefore, the instrument must be calibrated by varying these parameters. This can most conveniently be done in laboratory experiments where these factors can be precisely controlled.

Neutron well logging

We here consider only wells drilled in hydrocarbon reservoirs, although some of the technologies may also be used in fresh-water exploration and in geothermal energy production. There are several variations of neutron-based well logging. Some methods use isotopic neutron sources, and some apply neutron generators with 14 MeV neutron energy. In this text we will concentrate on neutron-based logging using neutrons from isotopic neutron sources. The main use of the neutron log is to provide porosity information of the near-well reservoir rock.

The well is drilled with the use of either water-based or oil-based mud with varying composition. A mud cake is built up on the well wall and mud filtrate is intruding into the near-well zone.

The porosity measurement is based on the assumption that the pore volumes in the formation rock is filled with either water or condensed hydrocarbon (oil). If free gas occupies some of the porosity, special corrections must be made to the instrument

Fig. 2 Principle of a portable equipment for measurement of soil humidity in the near-surface layer especially used in road construction and soil compaction work.

Fig. 3 Principle of a portable equipment for measurement of soil humidity used in the agricultural industry for irrigation control.

readings. The basic interaction is, as in the descriptions above, the slowing down of neutrons due to the collisions mainly with hydrogen atoms in the water and oil.

In neutron logging, some tools measure the epithermal neutrons, some the thermal neutrons, and some the gamma rays emitted when a neutron is captured by surrounding atoms.

Three methods are in use (Glover, 2014). These are

1. *The Gamma Ray/Neutron Tool (GNT)*: This tool has a neutron source and a single detector that is sensitive to high energy capture gamma rays (mainly from hydrogen and chlorine) and a detector for thermal neutrons. The tool is applied when centered in either open or cased holes. It is sensitive to, and must be corrected for, the borehole quality, drilling mud composition and mud cake thickness. The reading of the two detectors are both affected by the concentration of chlorine. This can give erroneous porosity values, which take the form of overestimated porosities.
2. *The Sidewall Neutron Porosity Tool (SNP)*: This tool can only be used in non-cased holes pressed against the well wall. The tool has a source and a single detector measuring epithermal neutrons. Since the cross section of chlorine for capture of epithermal neutrons is low, it is not particularly sensitive to chlorine contents of formation fluids. Source-detector spacing is ~ 40 cm. Rough well walls can cause misalignment of the tool and give erroneous readings.
3. *The Compensated Neutron Log (CNL)*: This tool carries a strong neutron source and two gamma-sensitive detectors spaced from the source at ~ 40 cm and ~ 65 cm, respectively.

The gamma detectors measure prompt gammas from the capture of thermal neutrons in hydrogen and chlorine. Thus, they are indirectly sensitive to thermal neutrons and at the same time to chlorine concentration, which must be corrected for. The tool is clamped against the well wall and can be used in cased holes. The measurement principle is recording of the difference in the thermal neutron population at the position of the two detectors. This difference is proportional to the concentration of hydrogen, which again is a function of the rock porosity. The principle of the CNL-method is illustrated in Fig. 4.

All tools need to be calibrated. The SNP and CNL tools are calibrated in blocks of limestone, sandstone and dolomite of high purity and accurately known porosity in test pits. They are calibrated to give the porosity directly in percent. Limestone is chosen as the calibrating lithology, so the readings are correct for limestone but need corrections for sandstone and dolomite or any other lithology. Fig. 5 shows an example of such corrected calibration curves.

Level gauging

Neutron back-scattering or back-diffusion techniques are also used to assess the status of tanks, silos, separators and other types of process equipment containing fluids and solid material of different composition. An example from the petroleum industry is given in Fig. 6, which shows the application of a neutron gauge to detect levels of different fluid fractions inside a fluid phase separator. Such large-scale process equipment is often opaque, thick-walled (2–3 cm) and made of metals like aluminum, titanium and steels. These metals are most often alloyed with other elements. Concentration of alloying elements may vary from 0.001% and below to 10s of %. Major alloying elements in steels, aluminum and titanium alloys are given in Table 2.

Fig. 4 Principle sketch of the Compensated Neutron Log (CNL) showing the combined wireline-operated tool with the neutron source and the two gamma detectors pressed up against the well wall for measurements.

Fig. 5 Example of CNL tool where the calibration is based on Limestone with corrections for Sandstone and Dolomite. Figure modified from Glover P (2014) "Petrophysics MSc Course Notes—Chapter 15. The Neutron Log", pp. 150–171, UK: University of Leeds, http://homepages.see.leeds.ac.uk/~earpwjg/PG_EN/CD%20Contents/GGL-66565%20Petrophysics%20English/.

Although fast neutrons from the neutron source easily penetrate the thick metal walls without noticeable disturbance, the host metal and alloying elements may absorb a fraction of the returning thermal neutrons, thus reducing the flux that hits the detector. In steel alloys the absorption will be dominated by the major element Fe, in titanium alloys with the major element Ti, but in aluminum alloying elements may play a bigger role. In fact, the thermal neutron absorption in the metals will lead to compound nucleus formation with subsequent emission of prompt gamma rays. The intensity of this gamma ray emission is proportional to the flux of thermal neutrons hitting the metal wall, which again is proportional to the hydrogen content inside the vessel at the gauge position. Thus, detecting the gamma rays is an alternative to monitoring thermal neutrons. That will, however, require a more sophisticated detector arrangement with energy-dispersive gamma detector with both high efficiency and sufficiently

Fig. 6 Principle sketch of a neutron-based back-diffusion gauge applied on a phase separator for produced fluids in the oil production sector. The gauge includes an isotopic neutron source and a detector for thermal neutrons. Panel on the left indicates how readings change with gauge position on the separator outer surface, mainly dependent on the hydrogen concentration in the interior fluid phases.

Table 2 Main construction host metals in process equipment for harsh conditions and their common alloying elements with the metal absorption cross section (σ) in bracket.

Main element in the metal (σ in b)	Common alloying elements (thermal absorption cross section σ in barn in brackets)
Iron, Fe (2.7)	Mn (13.3), Ni (4.5), Cr (3.0), Mo (2.5), V (5.0), Si (0.17), B (760) (Less common: Al, Co, Cu, Ce, Nb, Ti, W, Sn, Zn, Pb, Zr)
Aluminum, Al (0.23)	Mg (0.07), Si (0.17), Mn (13.3), Zn (1.1), Cu (3.8)
Titanium, Ti (6.1)	Al (0.23), V (5.0), Mo (2.5), Nb (1.1), Zr (0.19), Sn (0.61), Cr (3.0), Fe (2.7), Pd (7.0)

high energy resolution, which poses some challenges. Therefore, and so far, thermal neutron detection is the major detection technique for this type of application.

The technique described here is extremely useful in that access need only be to one side of the vessel. This makes it very quick. It is also accurate with a vertical resolution typically of a few cm.

Typical applications of a portable neutron-based back-diffusion gauge mounted on an extension pole, in addition to the application described above, include:

- Determination of storage tank sludge and inventory levels.
- Determination of moisture behind isolation in transportation pipelines to prevent corrosion attack.
- Determining liquid heights in distillation column downcomers and trays.
- Provisional level measurements in tanks, silos and separators during repair of permanently installed gauges.
- Calibration of permanently installed level gauges.
- Locate hydrate, wax, asphalt, polymer and other solids build-up inside process lines.
- Examine levels of deposits on the shell side of heat exchangers.
- Locate voids or lack of solid support under tank floors.

Neutron radiography and tomography

General

A common name for neutron radiography and tomography can be *neutron imaging*. That is the process of producing an image of an object with the use of a neutron beam. The result is based on the neutron attenuation properties of the imaged object. Unlike for X-ray and gamma ray imaging, where the image is mainly based on density contrasts where the densest material gives the highest attenuation. The neutron-based images are mostly sensitive to light materials, and especially to those containing hydrogen atoms. In addition, some elements with exceptionally high probability of absorbing thermal neutrons like boron (B), cadmium (Cd), indium (In), and the lanthanide metals samarium (Sm), europium (Eu), gadolinium (Gd), and dysprosium (Dy), and some other

chemical elements (see Fig. 1) will also induce strong attenuation. Thus, X- and γ -ray based methods and neutron-based methods are close to be complementary (see Fig. 7), and a combination of the two constitutes a strong imaging tool.

A neutron radiograph is a two-dimensional image, a projection, generated by neutrons of an object at rest. Traditionally, but even today, the final image is generated on a radiation-sensitive film, especially when pictures with high spatial resolution are required.

Neutron transmission tomography is the process of generating a three-dimensional image of an object with volumetric resolution. This can be done by turning the object in selected angle increments and recording a picture for each new position. This process is normally not using radiation-sensitive films, as it would be too time-consuming. A recent (2013) review of significant advances in neutron-based imaging over time is given in ref. (Brenizer, 2013).

Below, we offer a brief description of both neutron radiography and neutron tomography.

Neutron radiography

As mentioned above, neutron radiography is based mainly on the application of a radiation-sensitive film to create an image of the interior of an object. The film technology generally produces the highest resolution form of neutron imaging, although digital methods with pixelized detectors are recently achieving comparable results.

The principle of the imaging process is illustrated in Fig. 8. Here, an object of a homogeneous material (which in principle can be composed of several chemical elements) with sections of different thickness and with an imbedded oblate-shaped void is irradiated by epithermal or thermal neutrons. The penetrated neutrons are recorded in a detection cassette arrangement, which, as one of the

Fig. 7 Semi-quantitative illustration of the relative attenuation of gamma rays in different material and the corresponding thermal neutron attenuation in the same material. The smileys are not exactly to scale. They are solely meant to illustrate the attenuation tendency. Note the complementarity of the two imaging methods for hydrogen and lead.

Fig. 8 Principle sketch of simple neutron transmission through an object of a homogeneous material with different material thickness and with an imbedded void.

components, may contain a radiation-sensitive film. The transmitted neutron flux is at its highest where the material is thinnest, and there is also where the “blackening” on the film is strongest. The analogue film image so produced may be digitalized afterwards using light transmission scanners.

Images are normally not generated by detecting the penetrated neutrons directly on the radiation-sensitive film but by application of so-called conversion screens (Mix, 2005). There are mainly two types of screens applied; namely, the *direct transfer screen* and the *indirect transfer screen*.

The most frequently used approach for direct transfer of the neutron intensity applies a screen with gadolinium (Gd) homogeneously distributed over the screen area. Gd has a very high thermal neutron capture cross section, in particular due to the two stable isotopes ^{155}Gd with a natural abundance of 14.8% and a thermal cross section of $\sigma_{n,\text{th}} = 61,000 \text{ b}$ and ^{157}Gd with a natural abundance of 15.65% and a cross section of $\sigma_{n,\text{th}} = 254,000 \text{ b}$. When a screen of Gd is hit by thermal neutrons, (n,γ) -reactions will take place for all stable Gd-isotopes, and for the two mentioned the products will be the two *stable* isotopes ^{156}Gd and ^{158}Gd , respectively. Thus, very little radioactivity is generated in the screen, so the same screen can be used repeatedly. However, upon emission of the prompt γ -rays (corresponding to release of the neutron binding energy), conversion electrons will also be generated and emitted. The γ -rays are not of interest here. They are more of a disturbance and a nuisance. It is the conversion electrons (Bjørnstad, 2021b) that are important and utilized; they will “blacken” the radiographic film when the film is put in close contact with the conversion screen during neutron bombardment of the object. The “blackening” (upon film development) is most intense in areas where the neutron flux ($\text{n cm}^{-2} \text{ s}^{-1}$) is highest. Thus, a 2D projected image of the internal parts of object is directly, but also indirectly via the conversion screen, transferred to the film. Although other elements like boron (B), lithium (Li) and cadmium (Cd) may also be used as screen material, it is the Gd-screen that provides the best spatial resolution and the best contrast. Resolution can be as good as $100 \mu\text{m}$.

The indirect transfer screen works in a different way. With this method, the radiographic film is not mounted in the neutron beam path during object bombardment. Instead, a screen with another chemical element with a high absorption and *activation* cross section, is applied. The screen is mounted behind the object. Upon neutron bombardment of the object, the screen will be activated, i.e., radioactive nuclides will be generated in the screen. The activity distribution is proportional to the transmitted neutron flux. The optimum half-life of the generated activity is typically a few hours. After bombardment, the radioactive screen is dismantled and placed in close contact with the radiographic film. Beta particles emitted from the screen bombard the film for a period of several hours. Areal film “blackening” is proportional to the areal activity distribution of the screen.

The preferred chemical element for this process is dysprosium (Dy). During neutron irradiation, the stable isotope ^{164}Dy with a natural abundance of 28.26% and a thermal neutron cross section of $\sigma_{n,\text{th}} = 2650 \text{ b}$ will capture a thermal neutron and produce the radioactive Dy-isotope ^{165}Dy .

This radionuclide has a half-life of 2.33 h, and decays with relatively high-energy β^- - and low-energy γ -emission. This method is more work intensive and takes longer time than the one with direct transfer screens. However, it is particularly useful for the examination of objects that are very radioactive themselves. Examples are radiography of used nuclear fuel pins and other radioactive mechanical components from nuclear installations. The indirect conversion screen method is not affected by this radiation, while the direct conversion screen method is seriously affected and cannot be used.

Neutron radiography can be applied on objects over a large size range from a few mm to truck-load sizes. Its remarkable ability to look into and reveal “secrets” behind thick and heavy metal walls and where X-ray and γ -ray radiography would completely fail, is demonstrated in Fig. 9, where a pair of tulips have been imaged inside a thick lead casket.

Neutron transmission tomography

Neutron transmission tomography is a three-dimensional imaging technique of extended objects. It provides a map in two- and three-dimensions of the neutron attenuation coefficient distribution inside an object. Thus, the internal macroscopic physical structure and material composition as a function of volumetric distribution may be reconstructed and visualized as a volumetric image.

Fig. 9 Left panel shows a photo and right panel a neutron tomograph of flowers inside a lead casket. Picture in the Public Domain.

The principle of neutron tomography has been known and applied for a considerable time already. However, the use has gained special momentum over the last years due to the development of digital detection techniques based on position-sensitive detectors with high sensitivity and acceptable spatial resolution paired with increased power in computing for picture reconstruction.

The most common neutron source for radiography and tomography has, over time, been the research nuclear reactors. But today, large installation spallation sources, medium-installation LINACs with neutron-generating targets and small-installation sealed-tube fusion neutron generators with high primary neutron output ($>10^{13} \text{ n s}^{-1}$) have become available for these purposes as well. Fig. 10 sketches the principle of the main components in a measurement setup based on a nuclear reactor.

In general, tomography provides many more details of the internal structure of the object, compared to the radiography image. After the dataset has been taken, software tools allow researchers to make virtual slices of the object in all directions.

However, there is a price to pay for this increased and detailed information. Sometimes, longer data-taking acquisition time is needed in total because the computer-based reconstruction of the third dimension needs many (hundreds) of single projection images taken during rotation of the object. Needed extra computer time for the image reconstruction may be in the range of minutes to hours. The size of the dataset and the reconstruction algorithm used determines the time. Thus, when it takes a only few seconds to record a single neutron transmission image, the tomography results are only available in time ranges of hours. Therefore, it is worthwhile to consider the need for a tomogram, instead of a 2D radiograph, in order to solve the problem at hand. It is of course also possible to accept a lower resolution image. That will reduce the total time for acquisition reconstruction.

The text below provides some examples or snapshots where only neutrons or neutrons in combination with X-ray or γ -ray transmission or X-ray fluorescence are used for material and object examination in biology, archeology, studies of cultural heritage objects, fluid flow in porous media, defense material, space mission application, detection of explosives and illicit materials and detection of smuggling across borders (homeland security).

Applications in biology

Dead and living plants and animals and other biological specimens may be subject to neutron imaging applications. An example for the use on plants is the time-resolved examination of water and nutrient uptake by the root system grown in soil and how the root systems develops with time (Tötzke et al., 2019).

Another striking example is the microtomography of a dead and dried horsefly illustrated in Fig. 11. The details are striking, considering that the size of the object is only 12 mm. These images have been produced at the ICON—Cold Neutron Imaging Facility—at SINQ, Paul Scherrer Institut (PSI), Villigen in Switzerland (ICON Instrument: http://neutra.web.psi.ch/facility/icon_index.html). This facility pretty much represents the state-of-the-art in neutron microtomography. A detection system based on a solid scintillator was built with an inherent pixel size as low as $13.5 \mu\text{m}$ (Lehmann et al., 2011). Light transmission from the scintillator to the camera-based sensor was optimized to ensure best achievable detection efficiency. This device is heavily in use for micro-tomography at a beam position at about 6.5 m from the cold source.

Fig. 10 Principle sketch of a nuclear reactor with a cold-source to convert thermal neutrons to cold neutrons, a subsequent beam transportation channel for the neutrons, a turn-table arrangement for tomographic measurement of an extended object followed by a detector system for the transmitted neutrons. In this case, the main components in the detector system is a cassette with a radiation-sensitive film for radiography and a radiation- and position-sensitive scintillator coupled by light guides and a mirror arrangement to a CCD camera for efficient tomographic measurements.

The insect is approximately 12 mm long, and images have been taken with a resolution of 13.5 μm . Courtesy of Dr. Eberhard Lehmann, Paul Scherrer Institut, Switzerland.

Archeological and cultural heritage object examinations

In general, neutron radiography and tomography are often very useful for non-destructive examination and visualization of the internal structure of various archeological and cultural heritage objects embedded or not in other dense material non-transparent for visible light. The objective may be to verify its integrity, reveal hidden content and structure, assess the need of conservation and reveal restoration patches and manufacturing techniques.

A considerable fraction of available time for experiments on various neutron imaging facilities around the globe is dedicated to non-destructive study of archeological and cultural heritage objects (see also Varquez and Nagai, 2021). The literature in this area is overwhelming and specialized. To choose some examples of applications from the literature and leave others out feels nearly as a crime. Likewise, citing some references and leave others is also problematic. However, limited space for this article rules, and further reading to be enlightened in this area can begin with the references (Arif and Downing, 2006; Grabe et al., 2020; Kardjilov and Festa, 2017; Schillinger et al., 2018; Kichanov et al., 2018; Raymond and Bevitt, 2020; Festa et al., 2020).

The example chosen from archeology deals with tomographic examination of a mummified cat! The object was on loan to ANSTO (www.ansto.gov.au) from the Australian Institute of Archaeology (AIA) in Melbourne, Australia (Raymond and Bevitt, 2020).

The examinations comprised both X-ray and neutron-based computerized tomography (CT). Neutron CT appeared to be very useful for non-destructive studies of the ancient mummification techniques, and the neutrons revealed hidden contents otherwise not accessible. Both X-ray and neutron CT individually, and in combination, contributed to reveal valuable information on a partial skeleton, layers of different textile types and wadding and on bones and soft tissue (see Fig. 12). Results revealed age at death and that the animal remains belong to a small, juvenile feline.

Another example from this application area is the one represented by Fig. 13 below.

The object under study in this example is a small bottle made of red clay, with a smooth surface without any decoration. The bottle is 97 mm high and has a maximum diameter of 64 mm. A hieroglyphic seal is imprinted on its cap. The seal is identified as

Fig. 12 (A) Surface reconstruction of a neutron CT scan; (B) surface reconstruction of an x-ray CT scan; (C) X-ray reconstruction (red overlay) on neutron reconstruction background to show the orientation of skeletal remains within the wrappings; (D) neutron CT slice revealing layers of textile wrapping; (E) X-ray CT slice yielding higher grayscale contrast; (F) segmented and visualized calcaneus bone (green area in E); (G) close-up of area in d showing wrapping layers of different thicknesses and coarseness (red box on D). Figure is composed of single pictures from the “open access” ref. (Raymond and Bevitt, 2020).

Fig. 13 (A) Photo of a sealed Egyptian pottery (on loan from Museum of Aquitaine) and details of the seal with the emblem of Menkheperre Tuthmosis III, pharaoh of the Eighteenth Dynasty (1479–1425 BC); (B) X-ray CT 3D summary; (C) global front view obtained with neutron CT. In areas with red markers, prompt gamma activation imaging (PGAI) has been performed; (D) front views showing the mobile contents by rotation the pottery in three angles. The figure is composed of single pictures from the “open access” ref. (Abraham et al., 2014).

the emblem of Menkheperre Tuthmosis III (https://en.wikipedia.org/wiki/Thutmose_III), pharaoh of the Eighteenth Dynasty (1479–1425 BC) in ancient Egypt.

The bottle and its unknown content have been examined by three different tomographic techniques. These are the THz (Tera-Hertz), X-ray, and neutron imaging. Terahertz imaging utilizes electromagnetic radiation in the wavelength range of 0.1–1 mm. This is an emerging nondestructive evaluation technique used for analysis of non-conducting (dielectric) materials. It has also proved to be applicable in the inspection of layers in paints and coatings, detecting structural defects in ceramic and composite materials and imaging the physical structure of paintings and manuscripts. The main advantage of THz radiation is the possibility of rapid and rather cheap on-site nondestructive and noninvasive diagnosis, even if it is limited by a millimeter spatial resolution.

The three techniques are largely complementary. Applied together they provide a better understanding of the studied object. THz computed tomography revealed nondestructively the presence of some content, whereas X-rays and neutrons analyzed more precisely the fabrication process and conservation of the pottery together with the nature of this content. In addition to the neutron transmission tomography studies of the whole object, it was possible to carry out prompt gamma neutron activation analysis (PGNAA) on three selected portions of the bottle. The selected regions were: The stopper/cork region, the empty region and the region with the bottle content represented by the red frames in panel c of Fig. 13.

The neutron imaging application informed the way the object has been closed by a double stopper (clay and probably a ball of linen or any other string-like organic material) and provided a more accurate representation of the mobile and heterogeneous content, which may be constituted by germinated seeds (high carbon content).

The bottle may be of some importance as it may be directly linked to the funeral ritual of the diseased, possibly by offerings of food (or hope for good crops in the next world??).

Examination of fluid flow in porous media

The nature of fluid flow in porous media is an important subject in the petroleum industry. It is directly linked to the prospects of oil recovery from sedimentary reservoir rocks, which are mainly sandstones and two major types of carbonate rocks. Sandstones are composed of silicate (SiO_2) minerals and the two types of carbonate are limestone composed of calcite or aragonite (different crystal forms of CaCO_3) and dolomite ($\text{CaMg}(\text{CO}_3)_2$). These rocks are not smooth and homogeneous in the sense that the permeability field is constant and isotropic. On the contrary. The pore volume and pore size distribution vary with position, and larger particles of impermeable rock may be imbedded. This inhomogeneity, in itself, may lead to instability in the displacement front even when displacing one brine with another brine. When displacing viscous oil with less viscous brine, this instability may be amplified and develop into a fingering pattern resulting in poorer volumetric sweep by the water and correspondingly lower oil production. This type of challenges has also been discussed previously in Bjørnstad (2021a)) and Thereska and Brisset (2021b).

The general aim of the work in the example mentioned below has been to map imbibition and saturation of water during forced constant flux experiments (forced imbibition) in porous carbonate rocks of various pore structure. One of the goals has been to map the wetting front as a function of time as the flow proceeds through the rock samples, which are initially dry and air saturated. Thus, a significant contribution of capillary forces is expected since the rock grain surfaces are water-wetting.

The experimental methods used here comprise: X-ray tomography (XCT) (see Bjørnstad, 2021a) on dry cores to describe the structure of the solid rock; and time-lapse neutron radiography (NR) to harvest information on transport of the water and the movement of wetting front related to the effect of heterogeneities (e.g., fractures and deformation bands) at the microscale; neutron

tomography (NCT) on dry and fully water-saturated rock in order to generate more information on the effective pore space contribution to fluid flow. Experiments were simulated with computational fluid dynamics (CFD) calculations.

The flow experiments were carried out by enclosing the core(s) in a flow cell of non-transparent Teflon, which was a compromise to suit both for X-ray and neutron transmission experiments.

Results from the neutron radiography experiments are displayed in Fig. 14. From these experiments one may conclude that: (a) fractures presented in samples seen in the X-ray experiments generate a non-uniform flow front, indicating the presence of some anisotropy on permeability, and (b) in unsaturated samples, water fills rapidly part of the pore-structure. The front advances with a faster speed than expected from a homogeneous filling of the pore space. This may indicate a capillary force control of the flow in this front area. Towards the end of the experiments the samples are uniformly water-saturated until the fluid spills out. This indicate a control by the macropores on fluid flow and storage in continuous flooding operation.

Applications to cargo inspection

The smuggling and unlawful transport of illicit goods poses a significant threat to the safety, security and economy of all nations (see also Patton, 2021; Gozani and Sterlis, 2021). Freight containers are potential means for smuggling (e.g., tobacco), illegal immigration, trafficking of drugs, mis-declared goods and dangerous illicit substances, including explosives, nuclear material, chemical and biological warfare agents and radioactively contaminated goods. Cargo in such closed containers for air, ship and road transport is subject to non-destructive inspection and examination methods of various kinds, in order to reveal any illicit or contraband material.

Two of the non-destructive methods in use separately are X-ray or γ -ray transmission and neutron radiography. An even more powerful combined method is achieved when integrating the electromagnetic methods with the neutron methods. Such a combined method has been developed at CSIRO in Australia during the last years (Sowerby et al., 2009). An example of this is the combination of a source of ^{60}Co (γ -energies of 1174 and 1332 keV) with a DT neutron generator (neutron energy 14.1 MeV), where the intensity changes of the radiations in the penetrating radiations are measured (combined radiography methods).

With reference to Eq. (1) in (Bjørnstad, 2021a), and Eq. (2) in (Bjørnstad, 2021b), which describe the transmission probability of X-rays (or γ -rays) and the transmissions of fast neutrons, respectively, we may rewrite these equations slightly, take the logarithm and producing the ratio:

$$R = \frac{\mu_n}{\mu_\gamma} = \frac{\ln(I_{n,x}/I_{n,0})}{\ln(I_{\gamma,x}/I_{\gamma,0})} \quad (1)$$

Here, μ_n is the mass attenuation coefficient for neutrons used, μ_γ the mass absorption coefficient for the used γ -radiation, $I_{n,0}$ the detected intensity of the neutrons without the object present, $I_{n,x}$ the measured intensity of the neutrons with the object present, $I_{\gamma,0}$ the measured intensity of the gamma radiation without the object present and $I_{\gamma,x}$ the measured intensity of the γ -radiation with presence of the object.

Fig. 15 illustrates the R -values for different selected materials showing a variation that can be utilized for enhanced characterization of mixed cargo.

Fig. 16 is an illustration of a private vehicle that has been examined by a method developed recently by CSIRO in Australia in cooperation with a private company using a 6 MV X-ray machine and a 14 MeV neutron generator. This development has included

Fig. 14 Illustration shows the time-dependent neutron radiography of the flow profile of water injected in two air-filled carbonate cores with different grain size and pore structure: Core in panel to the left has much coarser pore structure than the core in panel to the right. Water enters from the bottom in these forced imbibition experiments. This type of measurements may reveal whether there is a homogeneous plug displacement or if fingering develops. Possible fluid channeling in fractures and indications of the contribution of capillary forces to the water migration may also be derived. The picture is composed of individual pictures from ref. (Zambrano et al., 2019).

new, non-linear filtering techniques to decrease noise and increase image definition. The time for image reconstruction has decreased down to a factor of 1/10 while preserving the image quality.

One technique alone or a combination of two techniques cannot cope with all possible situations that might occur. Several initiatives and developing programs have been initiated both in United States and in Europe (<https://www.cbord-h2020.eu/page/en/publications.php>) to develop sets of combined non-destructive and non-intrusive techniques to control cargo transport (see also (Patton, 2021; Gozani and Sterllis, 2021)). Even so, it is fair to say that implementation of such advanced techniques is still in their infancy. Further technical development and possible issues about safety regulations have to continue to be sorted out.

Neutron-based elemental analysis

General about PGNA

Ordinary neutron activation analysis, abbreviated NAA, most often involves the use of thermal and epithermal neutrons, and proceeds via compound nucleus formation with the (n,γ) -reaction illustrated in Fig. 4 in (Bjørnstad, 2021b). When neutrons from isotopic neutron sources or neutron generators are used, various other reactions may take place. This is illustrated in Fig. 5

in (Bjørnstad, 2021b). Common for ordinary NAA-techniques is the subsequent detection of radiation, preferentially γ -radiation, emitted from a formed radioactive nucleus. We may term this radiation as β - or α -delayed γ -emission. The emitted γ -radiation pattern (energy spectrum) is individual for each radionuclide and has its origin in the excited energy levels in the nucleus.

The fact that all nuclei (not only the radioactive ones) have individual excited energy level patterns forms the basis for another analytical technique termed *Prompt Gamma Neutron Activation Analysis*, or PGNA in short. PGNA can for instance be performed by irradiating the sample by thermal neutrons and detecting the prompt gammas emitted in the neutron capture process (the gammas in the (n,γ) reaction, Fig. 4 in Bjørnstad, 2021b). The gamma spectrum resulting after such interactions can also be regarded as a “fingerprint,” not only of the chemical element to be analyzed, but also of the individual stable isotopes of this element. The strong features of this method are its non-invasive and non-destructive nature and the fact that it does not depend on the generation of radioactive nuclei. The excitation energy available in this process is the neutron binding energy for the bombarding neutron in the target nucleus. Neutron binding energies in nuclei close to stability are generally in the range 4–8 MeV. Thus, excitation of high-energy levels (below the neutron separation energy) is possible.

Prompt gamma rays are also generated in inelastic scattering reactions with fast neutrons ($(n,n'\gamma)$ -reactions) and in particle-emitting reactions like $(n,p\gamma)$ -, $(n,\alpha\gamma)$ - and $(n,2n\gamma)$ -reactions (Fig. 5 in Bjørnstad, 2021b). The ability to populate excited states with these reactions in the various nuclei depends on the neutron energy. D-D neutrons with an energy of 2.45 MeV do not allow excitation of higher-lying levels than this energy.

Fig. 17 shows some examples of excited states in a few relevant stable nuclei, often in macro-concentration, which can be analyzed with PGNA from inelastic scattering reactions of fast neutrons.

The nuclei shown in Fig. 17 have all high energies for the first excited levels. These levels cannot be populated in D-D reactions (except from ^{14}N), but they can all be populated in D-T neutron (14.1 MeV) scattering reactions.

Fig. 18 illustrates a simple experimental setup for PGNA analysis. For a flexible and transportable experimental setup, the neutrons may come from an isotopic neutron source or a portable neutron generator (like in Fig. 18). The exact layout of the experimental setup can then be improvised and fitted to the actual situation. Using neutrons from these sources without thermalization allows for the generation of prompt gammas by inelastic scattering reactions.

Fig. 17 Simplified schemes of excited levels for the three abundant isotopes ^{12}C , ^{14}N , and ^{16}O of the three abundant chemical elements carbon, nitrogen, and oxygen, reflecting some of the most important excitation levels and the γ -rays resulting from these during deexcitation.

Fig. 18 Principle sketch of a PGNA experimental setup using neutrons from a neutron generator thermalized in a moderator before hitting the extended object.

Fixed PGNAA setups are often established at research reactors. Generally, higher neutron fluxes can be achieved, but only of thermal or cold neutrons. Thus, inelastic scattering reactions resulting in nuclear excitations are not possible. These setups are limited to utilization of the γ -rays emitted in the neutron capture process.

Sensitivities are not sufficiently high for most chemical elements for PGNAA to be characterized as an analytical technique for micro and trace elements. In the best cases, concentration in the low ppm range may be achieved. Still, it is a multi-element method for qualitative and quantitative analysis, but the particular strength lies in its ability to detect non-destructively light elements in bulky objects not easily achievable by other methods. A map of relative sensitivities for thermal neutron capture prompt γ -rays is provided in Fig. 19. Values on the lower limit of detection depend on a number of parameters, which may differ from one experimental setup to another. These include neutron flux, counting geometry, sample geometry, detector efficiency and energy resolution, etc. However, the general trend should be fairly similar for any setup applying thermal neutrons, and the values given may be considered as relative instead of absolute.

For quantitative analysis of a thin and small-size homogeneous object and for monoenergetic neutrons, the production rate R_p leading to the emission of a certain γ -ray energy is described by Eq. (2).

$$R_p = \sigma_\gamma \cdot \varphi \cdot N_T \quad (2)$$

Here, σ_γ is the partial cross section in barn for an excitation reaction that produces a defined γ -ray energy, φ is the neutron flux ($\text{cm}^{-2} \text{s}^{-1}$), and N_T is the number of target atoms of the analyte element. The counting rate involves a counting efficiency ε_γ composed of the counting geometry and the detector internal counting efficiency of the γ -ray energy in question. Hence, the counting rate R_c of a defined γ -ray energy is given by Eq. (3).

$$R_c = \sigma_\gamma \cdot \varphi \cdot N_T \cdot \varepsilon_\gamma \quad (3)$$

For extended objects the situation is more complicated. The neutron flux over the sample may vary ($\varphi(xyz)$) due to the self-shielding effect. In addition, the emitted γ -radiation is also subject to attenuation when penetrating the sample, and the degree of attenuation varies with the emission position ($\mu_\gamma(xyz)$). Further, if fast neutrons are applied and the sample consists of macro-amounts of light elements (plastics, aqueous or organic solutions), the neutron energy will also vary over the sample object ($E_n(xyz)$) and thereby also the reaction cross section ($\sigma_\gamma(xyz)$). For close distance between the extended object and the detector, the relative counting geometry will vary from different positions in the sample object and, thereby, also the counting efficiency ($\varepsilon_\gamma(xyz)$). The last factor is that the object may not be homogeneous, and then there is a volumetric variation also in the analyte

Fig. 19 Relative sensitivity of the PGNAA method for all chemical elements using thermal neutrons and detection of the prompt γ -rays from the neutron capture process.

concentration ($N_T(xyz)$). All these effects can be mathematically accounted for, but the present text is not the right place for an extended mathematical description.

Fig. 19 shows that one of the highest sensitivities for thermal neutron interactions is found for boron in the reaction $^{10}\text{B}(n, \alpha \gamma)^7\text{Li}$. The first excited state in ^7Li is at 478 keV, sufficiently low to be populated in reactions with all the relevant neutron energies.

This is, however, a special case. Because an α -particle is involved, the resulting 478 keV gamma line experiences a Doppler broadening. It is not appearing as a nice ordinary peak with normal energy resolution in the γ -spectrum. The size of the broadening is somewhat depending on the surrounding medium, broader in gases (like in BF_3) than in solid metallic boron.

The level energies and densities for the various isotopes of the chemical elements vary greatly over the nuclear chart. This is not the right place for a physical explanation of this variation, but a few general comments can be made.

For the lightest elements the excitation energies are in general higher than for heavier elements. Also, the level density for the first few MeV excitation energy is lower for the light elements than for heavier elements. However, close to magic numbers (Proton numbers 2, 8, 20, 28, 50, 82 and neutron numbers 2, 8, 20, 28, 50, 82 and 126) the situation is different. Examples of first excited states (energy in brackets) in magic proton number nuclides ^{58}Ni ($Z = 28$, 1454 keV) and ^{112}Sn ($Z = 50$, 1256 keV) and in magic neutron number nuclides ^{88}Sr ($N = 50$, 1836 keV), ^{138}Ba ($N = 82$, 1436 keV) and ^{140}Ce ($N = 82$, 1596 keV) all have higher first excited state than most of the surrounding nuclei. For the doubly magic nuclide ^{208}Pb ($Z = 82$, $N = 126$, 2614 keV), the first excited state is exceptionally high for a stable heavy nuclide.

With a high number of excited levels and a corresponding and even higher number of resulting gamma rays, the measurements may become a major challenge.

A gamma detector with high energy resolution is required if detailed spectroscopic measurements are deemed necessary. Fig. 20 shows the energy resolution achieved with three relevant gamma detectors (Seabury et al., 2006). The common, cheap and general purpose solid scintillator NaI(Tl) with a moderate energy resolution but high efficiency, the more expensive solid scintillator $\text{LaBr}_3(\text{Ce})$ with better energy resolution and even better efficiency and the semiconductor detector HpGe with the best energy resolution but lower efficiency for high-energy γ -rays.

An example of thermal neutron induced PGNAA on a real sample of natural rock minerals is shown in Fig. 21. The spectrum is accumulated with a NaI(Tl)-detector, and only the high-energy part is detailed enough for analysis revealing some of the macro-elements.

The neutron-based method described here is an essential part of the application examples that follow below.

Applications in the mining and mineral processing industries

World consumption of metals and other critical chemical elements like phosphorous are increasing. At the same time high-grade ores for some of these elements are decreasing. Thus, in order to meet larger demands, lower-grade and often inhomogeneous ores need to be mined. At the same time, the cost for mining and processing must be kept at reasonable levels. In response to these challenges, advanced online analytical techniques that support and ease selective mining and down-stream processing by better and faster characterization of ore composition are being developed and applied.

One may visualize the mining and further processing activities in a simplified way by the following steps (special procedure for metals):

Mining of rock → Crushing of rock → Transport to stockpile (on conveyor belt) → Separation of crushed rock according to mineral richness → Transport of rich rock to fine grinding → Flotation separation → Mineral dissolution → Chemical separation

Fig. 20 Gamma spectra from detection of prompt γ -rays from chlorine, hydrogen and nitrogen accumulated with the solid scintillators NaI(Tl) and $\text{LaBr}_3(\text{Ce})$ and the semiconductor detector HpGe. Redrawn from data in Seabury EH, Wharton JC and Caffrey AJ (2006) "Response of a $\text{LaBr}_3(\text{Ce})$ Detector to 2–11 MeV Gamma Rays", IEEE Nuclear Science Symposium, San Diego, California, October 29–November 4, 2006, INL/CON-06-11300 preprint, <https://inldigitallibrary.inl.gov/sites/sti/sti/4460701.pdf>.

step + ion exchange chromatography (liquid-liquid extraction) $\rightarrow$ Selective element elution $\rightarrow$ Electrowinning (of metals) $\rightarrow$ Smelting (of metals) $\rightarrow$ Final product.

Several of these processes are overseen by various sensing technologies comprising different nuclear methods. In this text, nuclear-based monitoring of two (three) of the steps in the industrial sequence above are briefly explained.

Mined ore is frequently transported on conveyors prior to stockpiling and milling and there is a need to analyze the ore with regard to ore grade and contaminating or otherwise disturbing chemical elements. Fig. 22 intends to show the principle of an industrial analytical setup where major elements in the crushed and grinded ore can be analyzed continuously and online on a running conveyor belt. Here, the analysis is based on the use of a 14 MeV neutron generator for generation of prompt γ -rays in inelastic scattering reactions. As opposed to the use of thermal neutrons for PGNA, this fast-neutron PGNA method is sensitive also to the contents of carbon and oxygen. In addition, it can be generally used for most of the chemical elements. Since the sensitivity is proportional to the reaction cross section, the sensitivities of some metals like B, Sc, Ti, Ni, Cd, Sm, Gd, Dy, Ho and some others are better for PGNA with thermal neutrons because of high cross sections for thermal neutron capture. This kind of measuring technology has only become possible in practice during the last 10–15 years due to the recent years' development of small portable neutron generators and has still not "invaded" globally the mineral processing industry.

Fig. 22 Online analytical setup for bulk analysis of grained ore transported continuously on a conveyor belt. The method is based on PGNA using fast neutron from a neutron generator.

Another step in the mineral processing sequence is the chemical separation steps where liquid-liquid extraction, also termed solvent extraction, traditionally has constituted one of the major methods. It starts with the metal ore dissolved as ionic components in an aqueous solution (acidic or basic), complexation of the element (metal) of interest with a complexing agent, which makes the complex lipophilic and subsequent extraction of this lipophilic metallic complex into a contacting organic solution. Purification may take place in several steps, where the organic complex is back-extracted (stripped) into a new (virgin) aqueous phase, extracted again into an organic phase and so on. In each extraction step, contaminating elements lose ground and are finally reduced below the defined tolerance or concentration limit. The needed number of steps varies with the specific chemical procedure involved but can easily be >10 – 20 and even more. The process is illustrated in Fig. 23.

The elemental concentration in the various fluid streams in this industrial separation system may be overlooked by the use of neutron-based methods, and especially by the use of small portable neutron generators. Fig. 24 shows three principles for detection of elemental content of process fluids, which may be used at various stages in the chemical processing system of Fig. 23. The three methods are:

1. The first method in the left panel utilizes the transmission efficiency of thermal neutrons, and the targets for detection are chemical elements with a high thermal neutron absorption cross section like B, Sc, Ti, Ni, Cd, Sm, Gd, Dy, Ho and more. The intensity of the transmitted neutrons will decrease with increase in concentration of these elements. For small tube or pipeline diameters (<10 cm), it may be necessary to slow down the neutrons from the neutron generator by an external moderator (not shown in the figure).
2. The second method shown in the left panel is simply PGNA, with detection of prompt γ -rays generated both by thermal neutron absorption reactions and by inelastic scattering reactions. Both these methods are true non-intrusive, continuous and online adaptable methods.

Fig. 23 Principle scheme of a chemical separation system based on solvent extraction with mixer-settler equipment where the element of interest (red circle) is separated from the contaminants (green and yellow circles) in a number of extraction/stripping steps.

Fig. 24 Panel to the left: The figure sketches two neutron generator-based techniques for analysis of elemental content in fluid flows of process fluids,—one based on neutron transmission with detection of transmitted neutrons and one based on PGNA with gamma detection. Panel to the right: Special analytical technique of elements with high neutron capture cross section based on activation of a stationary activation metallic foil in a pulsed neutron beam.

3. The method in the right panel is also applicable for analysis of chemical elements (in macro-concentration) with a high cross section for interaction with the neutrons over an extended energy scale from fast to thermal energies. It is based on activation of a permanently installed “activation foil,” preferably a metal, which upon bombardment by neutrons from a neutron generator produces ultra-short-lived radionuclides with half-lives in the nanosecond (ns) to millisecond (ms) range. The neutron generator must be pulsed with a pulse duration in the low ms range. After a neutron pulse, the analytical system is silent for some picoseconds in order to get rid of any generated prompt γ -rays. Then it starts recording γ -radiation from the induced ultrashort-lived radionuclides in the activation foil for a period of 1–3 half-lives. Then a new neutron burst is generated, and the counting sequence repeated and so on. The concentration of the analyte in the flowing liquid is *inversely* proportional to the recorded intensity of the γ -radiation from the activation foil.

The fluid sample in point 3 above is considered homogeneous. The counting rate R_c from the generated activity in the activation foil may then be described by Eq. (4).

$$R_c = R_p \cdot \varepsilon_\gamma \cdot \left(1 - e^{(-\lambda t_i)}\right) \cdot e^{(-\lambda t_d)} \quad (4)$$

Here, R_p is the effective production rate of the radionuclide in question, ε_γ is the counting efficiency of a selected γ -ray energy, λ is the decay constant ($\ln 2/T_{1/2}$) of the radionuclide, t_i the irradiation time of the neutron burst and t_d the decay time from stop irradiation to start counting.

Candidate radionuclides to be generated in an activation foil are listed in Table 3. The methods described here must be regarded as “emerging” since some technical development remains.

Non-destructive mapping of element spatial distribution of extended objects

As mentioned previously in (Bjørnstad, 2021b), a DT-neutron generator is based on the nuclear reaction $^3\text{H}(\text{d},\text{n})^4\text{He}$, i.e., an α -particle is produced along with the neutron. This alpha particle is emitted in a direction 180 degrees opposite to each fast 14 MeV neutron produced. The α -particle has a kinetic energy of 3.5 MeV and moves back-to-back with the neutron in the center-of-mass system. In a modified form of the DT generator, these α -particles can be detected internally with a position-sensitive segmented (multipixel) array detector. By localizing the α -particle trajectory, the direction of the corresponding neutron is also determined. In addition, the multipixel α -detector will provide a time-tag for the α -particle generation, and of the accompanying neutron, as well as the direction relative to the neutron-generating deuterium target. Therefore, the direction of the accompanying neutron is also determined. The fast neutrons thus produced are, therefore, also defined as “tagged” (by the alpha particle), in time as well as in direction.

These neutron generators, with built-in α -particle detectors, are possible to apply for the identification of the volumetric distribution of selected chemical elements in extended objects with high sensitivity and position resolution. The neutron collides with a nucleus in the material under study and produces a prompt γ -ray, whose time of arrival at a position-sensitive and pixelized gamma detector can be precisely measured. This is, therefore, a Time-of-Flight (TOF) method that allows for the determination of the distance traveled by the neutron (as both the speed of the neutron and that of the γ -ray are known). Since its direction is also known, a three-dimensional volumetric resolution of elemental distributions in extended objects can be provided. This is then a form of tomography. The principles are sketched in Fig. 25.

Table 3 Some nuclei with ultra-short-lived isomeric states in the half-life region nanoseconds to microseconds, and which decay with measurable gamma energies.

Fig. 25 Principle sketch of a 14 MeV neutron generator with a pixelized position-sensitive α -detector (the associated particle detector), for the α -particle generated in the $T(d,n)^4\text{He}$ reaction. The neutrons induce prompt γ -rays in an external extended object on a straight line determined both by the α -detector and a neutron detector array behind the sample. The position of the γ -emission in the object will then be determined by a collimated and position-sensitive gamma detector with spectroscopic properties.

Due to the use of an α -particle signal as a natural trigger, there is in principle no need to use a pulsed neutron generator for coincidence measurements. Instead, compact DT neutron generators with continuous Penning ion source can be used without expensive and heavy high-voltage pulse electronics. In some types of applications, the neutron production rate might even have to be kept low, so neutron interactions do not interfere in order to limit random coincidences.

Detection of the associated alpha particle requires that an alpha detector be built into the neutron tube. This places stringent requirements on the alpha detector material and design in that it must withstand the temperatures used in processing the neutron tube without introducing contaminants into the tube. Alpha detectors should also have very high radiation hardness for reliable operation during the lifetime of the sealed tube, which should be several thousands of hours. At present, neutron generators with built in alpha particle detectors can be provided by several companies, and we have until now only seen the beginning of the use of such equipment.

Various neutron-based applications in the defense industries

Ammunition and power devices based on explosives

Metallic capsules with energetic explosives are important in several areas, not least within the defense sector. For instance, they will power the instant removal of the canopy of a fighter plane and eject the pilot in case of emergency. In rockets that send satellites into orbit, similar explosive charges in the payload fairing separation system allow release of the payload. In war-related and similar conflicts the reliable operation of personal defense weapons like shotguns may be essential for the individual security. Thus, one must trust in the gun at hand and the corresponding ammunition. A single energetic device misfire can make the difference between success and a disastrous failure.

Such power devices, however, consist mostly of a dense outer shell encasing the powdery or solid compound mixture consisting largely of lighter chemical elements. Therefore, they are difficult to inspect for flaws with most methods for non-destructive testing. Defects such as lack of proper filling and voids, cracks, gaps and bubbles in the filling, can lead to misfires. However, the inspection is facilitated by using neutron radiography as illustrated for shotgun ammunition in Fig. 26.

Landmine detection

Landmines have over time been developed and used for two main purposes:

1. To create defensive tactical barriers, channeling attacking forces into predetermined fire zones (as in the Finnish defense against Russian invaders during the second world war) or slowing down an invading force's progress to allow reinforcements to arrive.
2. To act as passive area-denial weapons (to deny the enemy use of valuable terrain, resources or facilities when active defense of the area is not desirable or possible).

Landmines have been designed both for vehicles (tanks, trucks etc.) and for personnel to injure and kill.

Anti-personnel mines were, however, banned with an international treaty known as the *Ottawa Treaty* (https://treaties.un.org/Pages/ViewDetails.aspx?src=IND&mtdsg_no=XXVI-5&chapter=26&clang=_en) in 1997, and during the following years the

Fig. 26 X-ray (top) and neutron (bottom) image of shotgun ammunition. Note the difference in contrast where the X-rays image illustrates metal density, while neutrons are capable of penetrating nearly undisturbed through metals to image light-element materials in the gunpowder. Courtesy of Dr. Eberhard Lehmann, Paul Scherrer Institut, Switzerland.

majority of such mines were destroyed in the 164 nations that, to date, have signed the treaty. However, these do not include China, the Russian Federation, and the United States (<https://www.apminebanconvention.org/states-parties-to-the-convention/>).

As of 2013, the only governments that still laid landmines were Myanmar in its internal conflict, and Syria in its civil war (*The Economist*, 2013) but as of 2019, non-state armed groups have used landmines in additional 6 countries (*Briefing Paper*, 2019).

Despite the mentioned reduction in landmine inventory, buried and forgotten landmines still present a permanent humanitarian threat. It is estimated that there are over 110 million landmines scattered in over 78 affected countries in different regions of the world. In the period 1999–2017, more than 120,000 casualties were recorded, and countless number of people were injured.

Demining of previous battle fields is of high priority and importance but can be a tedious and dangerous work. Using traditional partly manual methods such as metal detectors, prodding and dogs is not sufficiently effective and safe. In addition, reasonably modern landmines are mostly made of plastics as opposed to older mines that contained substantial metallic parts. Thus, they cannot be detected with metal detectors.

Considerable resources have been allocated in several countries to develop new technology for landmine detection. One of the most successful and efficient developments is based on the use of neutrons. Three of the most common explosives are listed in *Table 4*. They are all composed of hydrogen, carbon, nitrogen and oxygen in various proportions. Thus, the solution to the problem of explosive identification may be based on identification of light elements suitable for neutron interaction techniques.

There are two techniques of main interest: (1) the application of thermal neutrons to detect nitrogen by thermal neutron capture and subsequent detection of prompt gamma rays, and (2) the use of fast (14 MeV) neutrons in inelastic scattering reactions followed by detection of the prompt gamma radiation for identification of all four elements.

Table 4 Three of the most common explosives in landmines.

Name/acronym	Sum formula	Structural formula
Trinitrotoluene/TNT	$H_5C_7N_3O_6$	
Cyclotrimethylene-trinitramine/hexogene/RDX	$H_6C_3N_6O_6$	
Pentaerythritol-tetranitrate/pentrite/PETN	$H_8C_5N_4O_{12}$	

Advantages of the first technique are: A relatively high neutron capture (n, p) cross section for nitrogen (1.93 b) paired with gamma emission in a high-energy region not substantially disturbed by prompt radiation from other elements (10.83 MeV). This offers a high and reliable sensitivity. The transportable neutron source may be ^{252}Cf or a neutron generator based on the DD-reaction, both equipped with a neutron moderator to slow down the neutrons to thermal energies. It is not appreciably disturbed by the common nitrogen content in soil of around 0.1%.

The second technique allows, in principle, detection of all four elements. However, it must overcome possible disturbances from soil humidity and an avalanche of γ -rays of other elements in the soil. A good energy resolution of the γ -ray detector may be more important than a high counting efficiency.

The demining process has nowadays become partly motorized and semiautomatic. Fig. 27 illustrates the principle of a remotely operated vehicle equipped with a neutron source and γ -ray detectors hunting for buried landmines. More details about neutron-based landmine detection can be found in refs. (Kregar, 2016; Cousins et al., 1998; Takahashi et al., 2011; Csikai et al., 2004).

Detection of illicit materials

Here we consider mainly illicit traffic of drugs and explosives. The detection of such concealed contraband has been based mainly on the use of X-rays, vapor detection by gas chromatography and sniffer dogs. However, since the principal elemental constituents of narcotic and explosive substances are the light elements hydrogen (H), carbon (C), nitrogen (N) and oxygen (O), the sensitivity of X-rays for these elements with low electron and mass densities is limited.

In addition, these materials are not easily detected by shape recognition because they can be formed in any shape and “hidden” behind cloths and other ordinary materials in suitcases and other types of closed containers.

This is particularly a problem in inspection of baggage for air transport. Here, the tolerance is zero for not detecting explosives when it is present.

The use of neutron-based technologies for the elemental analysis of these types of materials is a viable alternative. Fig. 28 shows that the principal elemental constituents of narcotic and explosive substances differ strongly from one-another. Explosives contain relatively high proportions of nitrogen and oxygen and relatively low proportions of carbon and hydrogen, as opposed to illicit drugs, which are generally rich in hydrogen and carbon and poor in nitrogen and oxygen.

Over the last two decades there has been much interest in exploring the use of neutron methods for the non-destructive and non-intrusive detection of explosives and illicit drugs—both in airline baggage and in large cargo containers. Such methods have already been in use for years at several locations, but methods are still continuously under development for improvement in speed, sensitivity and resolution.

Methods in use include thermal neutron-induced PGNA (isotopic neutron sources and neutron generators), fast neutron-induced PGNA (neutron generators), fast neutron induced PGNA with time and direction tagged neutrons (neutron generators with associated particle detection as sketched in Fig. 25), combined fast neutron and gamma radiography (neutron generator and gamma source).

Fig. 27 Principle sketch of a motorized and remotely operated vehicle for detection of buried landmines. It is equipped with a set of gamma detectors and an isotopic neutron source (for instance ^{252}Cf) or a neutron generator of the DD (2.5 MeV neutrons) or DT (14 MeV neutrons) type. Neutrons from the two first neutron generating devices are slowed down to thermal energies before use in neutron capture reactions. The 14 MeV neutrons are used in PGNA based on inelastic scattering.

Fig. 28 Elemental composition of common explosives (upper panel), common drugs (mid panel) and other common materials (lower panel) that may be transported along with the illicit material. One observes that the relative concentrations of hydrogen, carbon, nitrogen and oxygen differ considerably between the various compounds, and this difference is basis for concealed drug and explosives detection.

Perhaps the most interesting and promising is pulsed fast and thermal neutron induced PGNA combined with detection of decay γ -rays. Further details of this technique are as follows:

Consider a situation with a concealed package with unknown but suspected content of illicit material. A pulsed sealed tube neutron generator, which produces a train of 14.1 MeV neutron pulses (DT generator), may be used here to reveal hidden secrets. Each neutron pulse has a duration of a few μ s. The inelastic scattering of the fast neutrons on elements like C and O produces prompt γ -emission with good sensitivity and main energies at 4.44 and 6.13 MeV, respectively. For each neutron pulse these are recorded with suitable γ -detectors, analyzed and stored. The sensitivity for H and N with fast neutrons is, however, not very high, so a "trick" must be performed. After recording of the prompt γ -rays (picosecond duration) a waiting time of about 100 μ s for the next neutron pulse is introduced. During this time a portion of the neutrons have slowed down, and some have become thermalized. Thermalization time for 14 MeV neutrons in an extended volume object with a considerable hydrogen content is in the order of 10–20 μ s. Thermalized neutrons are captured with usefully high cross sections by elements like H, N, Cl and P, and prompt γ -rays are emitted, detected, analyzed and stored in a file separate from the previous one. For H the important energy is 2.22 MeV and for N 10.83 MeV.

This procedure is repeated with a frequency of approximately 10 kHz. After a few hundred pulses, the neutron beam is turned off for a short period (3–5 ms). During periods with neutron pulses some short-lived radioactive components have partly grown in, the

decay γ -rays (β -delayed γ -emission) are detected after both the fast and thermal neutron induced prompt γ -rays have died away, analyzed and stored in another file separate from the two previous ones. Induced radioactive components from the presence of O will be ^{16}N ((n,p)-reaction on ^{16}O , $T_{1/2} = 7.13$ s, $E_\gamma = 6.13 + 7.12$ MeV), presence of F may generate the same radionuclide ((n, α)-reaction on ^{19}F) and in addition ^{19}O ((n,p)-reaction on ^{19}F , $T_{1/2} = 26.5$ s, $E_\gamma = 197 + 1357$ keV) and the presence of silicon, Si, may be visible through ^{28}Al ((n,p)-reaction of ^{28}Si , $T_{1/2} = 2.25$ m, $E_\gamma = 1779$ keV). Hence, by combining three different techniques, i.e., inelastic neutron scattering followed by prompt γ -ray emission, thermal neutron capture followed by prompt γ -ray emission and delayed neutron activation analysis, all the relevant light and several other chemical elements contained in an object can be measured in a continuous and non-intrusive mode without the need of sampling. Thus, illicit material may be discovered in the closed and sealed containers.

Applications for “homeland security” purposes

This section deals exclusively with the illicit transport and trafficking of radioactive and so-called “nuclear” material, where the term “nuclear material” is taken to comprise fissile (by thermal neutrons) and fertile materials (definitions are given in the text below). See also (Patton, 2021 and Gozani and Sterlis, 2021).

Control of unlawful transport and proliferation of radioactive and nuclear material has been internationally recognized as one of the most important concerted actions to take. The most direct proliferation threat has been seen to involve the transfer of completed nuclear weapons from one State to another. However, quite apart from the question of preventing transfers of complete explosive devices, there is a need to prevent transfers of radioactive and nuclear material as a whole (IAEA, 2007).

By radioactive material, in this connection, is meant longer-lived radioactive nuclei, which have the potential of contaminating large land areas when mixed with conventional explosives (like TNT) as “dirty bombs.” Such materials can also be dispersed by airplanes and drones or manually be put into reservoirs of drinking water. Examples of γ -emitting radionuclides (half-life in brackets) produced in considerable amounts mainly for industrial applications, but which can also be used in dirty bombs, are ^{57}Co (272 d), ^{60}Co (5.3 y), ^{75}Se (120 d), ^{133}Ba (10.6 y), ^{137}Cs (30.1 y), ^{152}Eu (13.5 y), ^{192}Ir (73.8 d), and ^{241}Am (432.6 y). Examples of corresponding pure β -emitters, which cannot easily be detected outside closed containers are ^{14}C (5730 y), ^{35}S (87.4 d), ^{63}Ni (100 y), and ^{90}Sr (28.9 y), while examples of α -emitters, are ^{210}Po (138.4 d), ^{226}Ra (1600 y), and ^{241}Am (432.6 y).

On border crossings, fixed radiation portal monitors (RPMs) are pass-through type monitors typically consisting of two pillars containing γ -radiation detectors both for vehicles, smaller pieces of goods and people, while pure β - and α -emitters cannot be seen by such equipment. These detectors do not necessarily exhibit spectroscopic properties, i.e., they are not able to accumulate energy spectra. However, they can be backed up by multipurpose handheld instruments for this purpose. Still, transport of illicit materials may be covered up, purposely or not, by lawful transport of the mentioned types of radionuclides aimed for industrial applications and transport of radionuclides for use in hospitals (nuclear medicine). These latter types of radionuclides are relatively short-lived and cannot effectively be used in dirty bombs. Examples of such radionuclides used in human examinations are ^{18}F (109.7 m), ^{67}Ga (78.3 h), ^{68}Ga (270.9 d), $^{99\text{m}}\text{Tc}$ (6.0 h), ^{111}In (2.8 d), ^{123}I (13.2 h), ^{125}I (59.4 d), ^{131}I (8.0 d), and ^{201}Tl (3.0 d). Other lawful transport of slightly radioactive material is goods containing naturally occurring radioactive material (NORM) mainly represented by ^{40}K (fertilizers, additives to drilling mud, foodstuff like bananas etc.) and the natural radioactive series originating from ^{238}U and ^{232}Th (raw materials/minerals for production of rare earth metals, building front cover bricks of granite, and tiles for road sidewalk pavement of granite).

However, the technology for detecting radioactive illicit material on a background of lawful radioactive material transport that does not involve neutron interrogation methods will not be further discussed here. Rather, the remainder of this section will be allotted to neutron-based methods for interrogation of illicit transport of nuclear material. Nuclear materials may be divided into two classes:

1. Those radionuclides or combinations of radionuclides that are fissionable by thermal neutrons and may be used for the development of a nuclear weapons. These include ^{233}U ($T_{1/2} = 1.59 \cdot 10^5$ y), ^{235}U ($T_{1/2} = 7.04 \cdot 10^8$ y) and ^{239}Pu ($T_{1/2} = 24,110$ y).
2. Radionuclides that can be used to produce fissionable materials. Those are said to be fertile. These include ^{232}Th ($T_{1/2} = 1.40 \cdot 10^{10}$ y) and ^{238}U ($T_{1/2} = 4.47 \cdot 10^9$ y). The first is raw material for production of ^{233}U by the reaction $^{232}\text{Th}(n_{\text{th}},\gamma)^{233}\text{Th} \rightarrow \beta^- \rightarrow ^{233}\text{U}$, and the second is raw material for production of ^{239}Pu by the reaction $^{238}\text{U}(n_{\text{th}},\gamma)^{239}\text{U} \rightarrow \beta^- \rightarrow ^{239}\text{Pu}$.
3. However, ^{232}Th and ^{238}U are also fissionable with high-energy particles like 14 MeV neutrons from a neutron generator.

The detection of concealed contraband items is a difficult challenge in most contexts. In many cases the contraband may constitute only a very small fraction of the total mass of the object being interrogated and screening often needs to be carried out rapidly. Here are a few brief descriptions of some non-intrusive neutron-based methods which have been developed or are still under development in order to meet these challenges.

- (a) *Spontaneous fission neutrons from uranium*: Passive detection of neutrons originating from spontaneous fission of ^{238}U , which has a spontaneous (unprovoked) fission decay branch of $5.4 \cdot 10^{-5}\%$. A sample of depleted uranium, ^{238}U , of 1000 cm² (corresponding to a weight of 19.16 kg) emits ~ 260 n s⁻¹. Significantly higher amounts than this of depleted uranium may be

transported in the same batch. Hence, this is readily detectable with a portal arrangement of high-efficiency neutron detectors (often based on ^3He - or plastic scintillators).

- (b) *Spontaneous fission neutrons from plutonium*: The spontaneous fission branch of the fissile radionuclide ^{239}Pu is only $3 \times 10^{-10}\%$, resulting in a neutron emission of only 6.9 n s^{-1} for a sample of 1 kg corresponding to a volume of 50.6 cm^3 . Samples much larger than this is not expected to be transported in one batch since the criticality of ^{239}Pu is around 10 kg. However, chemically processed plutonium may also contain sizable amounts of the heavier isotope ^{240}Pu ($T_{1/2} = 6561 \text{ y}$), which has a spontaneously fission branch of $5.7 \times 10^{-5}\%$. For a 1% (= 10 g) content of ^{240}Pu in 1 kg of ^{239}Pu , the neutron emission amounts to $4.8 \times 10^4 \text{ n s}^{-1}$. Normally, the isotopic ratio of ^{240}Pu is higher than 1%: Plutonium is graded by the proportion of ^{240}Pu : weapons grade (<7%), fuel grade (7–19%) and reactor grade (>19%). Therefore, samples containing chemically processed plutonium will be readily detectable by passive detection of the emitted neutrons from spontaneous fission of ^{240}Pu .
- (c) *Application of fast neutrons, the “nuclear car wash”*: Trucks with cargo containers to be inspected are towed along a track that passes the interrogation portal consisting of neutron generators (for instance with 14 MeV neutrons) on both sides together with a battery of gamma and neutron detectors (Fig. 29). Upon neutron interaction with the cargo, three effects may be observed and used to disclose the nuclear contraband:
1. Detection of high-energy γ -radiation (> 3 MeV) from short-lived fission products induced by a burst of fast neutrons from both fissile and fertile materials. The interesting half-lives are in the range 0.1 s to a few minutes. Prompt γ -rays from neutron interactions with other materials in the cargo are not disturbing because of a short delay from end of neutron burst till start of detection. Likewise, gamma radiation from natural sources is not interfering since the highest energy of some importance from natural radiation is 2.614 MeV and, therefore, not within the selected counting window. It can be argued that γ -radiation can be shielded and strongly attenuated either in passive high Z/high density shields or in the rest of the cargo in the container. However, for standard size containers (cross sections $D = 235 \text{ cm}$, $H = 239 \text{ cm}$) one has found that the maximum loading for an authorized road transport (weight limitation) is $\sim 0.86 \text{ g cm}^{-3}$ for a 20 ft. (5.87 m) container. For a centrally positioned γ -source, this corresponds to a mass density over the 117.5 cm distance to the container outer surface of 100 g cm^{-2} . In practice, mass density of actual loading in commercial traffic is in the range $0.1\text{--}0.3 \text{ g cm}^{-2}$ (Slaughter, 2016). These mass thicknesses are readily penetrated by high-energy γ -radiation. One advantage with this method is that high energy resolution of the gamma detectors is not required. Typically, several half-lives are registered in the counting window. Their decay characteristics may help to identify whether the target is highly enriched uranium, depleted uranium or plutonium, as these species have significantly different fission product yield distributions.
 2. Detection of β -delayed neutron emission from the fission products is also possible. If passive shielding against the induced γ -radiation has been implemented in the transported cargo, this may be the alternative method of choice, since neutrons penetrate normal shielding material for γ -radiation. The β -delayed neutron yield per fission for ^{235}U is ~ 0.015 , while that for ^{238}Pu is ~ 0.0061 . Half-lives of the neutron-emitting fission products are in the range of milliseconds to a few seconds. With a pulsed neutron generator with a pulse frequency in the range 0.1–10 Hz, repeated counting cycles can be performed on the same object while passing the interrogation portal, thus enhancing the sensitivity of the examination.
 3. Depending on the arrangement of the neutron detectors, a rough neutron tomogram may also be accumulated (see “Neutron transmission tomography” section earlier in this chapter). This may add positively to the experimental data inventory for detection of concealed contraband.

Fig. 29 Truck with cargo in sealed container are towed through an interrogation portal where the cargo is irradiated with beams of fast neutrons (like water in a car wash) to produce fission in fissile and fertile material concealed within the cargo. The portal also contains detectors for neutrons and γ -radiation.

The neutron-based “nuclear car wash” methods may be assisted by application of strong collimated γ -sources (for instance ^{60}Co) to reveal any high-density spots or volumes, for instance an active γ -shield, in the cargo (see The gamma transmission method in Bjørnstad, 2021a).

Applications in space research

The following text will concentrate on one example only: The Curiosity mission to Mars, launched by NASA, to measure evidence of water in Mars’ soil.

Already in 2004, the twin rovers Spirit and Opportunity discovered evidence that the planet Mars once hosted running water before becoming a frozen desert. This was a ground-breaking discovery. If there has been water, there might also be evidence of organic biological life. But when did this happen and why?

In order to improve data quality and, thereby, more solid conclusions, NASA launched the Curiosity mission (<https://mars.nasa.gov/msl/home/>) on November 26, 2011 carrying a supersized rover (Fig. 30) to learn more. It landed in the Gale Crater on Aug. 5, 2012. The rover carried various types of instrumentation, also comprising a pulsed 14 MeV neutron generator with a neutron output of 10^7 n/s and a corresponding ^3He -based neutron detector. This instrumentation, named DAN (Acronym for “Dynamic Albedo of Neutrons”), was developed and optimized for the space mission by Russian scientists. The rover and its instruments were powered by nuclear energy based on the radioactive decay of ^{238}Pu (Bennett, 2021a,b).

Thus, one of the question Curiosity was set out to answer is: did Mars ever have the right environmental conditions to support small life forms called microbes? The neutron generating and detecting instrumentation was included to analyze for hydrogen in the soil as a sign of water or hydroxyl (OH) as a prerequisite for life down to a maximum depth of 1 m. The analytical method is neutron scattering and back-diffusion spectroscopy, similar to that described previously in *Soil water content* and *Neutron well logging*. But neutron activation coupled with gamma spectroscopy was also used.

For the neutron scattering method the principle is in brief: The neutrons emitted from the neutron generator penetrate into Martian soil to interact with the nuclei of main rock-forming elements through several reactions including (n,n') , $(n,2n)$, (n,p) , (n,α) and (n,γ) . As a result of scattering interactions, fast neutrons are slowed down and lose part of their energy. Some of the moderated neutrons are absorbed in the subsurface, while the other part scatters and diffuses back. A fraction of these are registered by the neutron detector in a short period (milliseconds) after each neutron pulse as the time decay curve of the neutron flux. The returned epithermal neutrons have a short time distribution, while neutrons in the thermal region (who have had multiple collisions with hydrogen atoms) show a wider time distribution (Fig. 31). A high intensity of neutrons with back-diffusion times longer than ~ 2 ms is a sign of the presence of hydrogen.

The rover carried out detailed studies at the landing site, the Gale Crater, and then set out on a long journey to analyze soils in different areas and collect physical soil and rock samples. On August 19, 2015, NASA scientists reported that the DAN had detected an unusual hydrogen-rich area, at the so-called “Marias Pass,” on Mars. The hydrogen found seemed related to water or hydroxyl ions in rocks within 1 m beneath the rover. This indicated that the amount of hydrogen was three to four times as high as the amounts detected anywhere previously along Curiosity’s traverse of about 6.9 miles (11.1 km) since landing in August 2012. The hydrogen detected by DAN is interpreted as water molecules or hydroxyl ions bound within minerals or water absorbed onto minerals in the rocks and soil.

Fig. 30 The Curiosity rover for the NASA Mars mission launched in 2012. Insets are the pulsed 14 MeV neutron generator and the corresponding ^3He -based neutron detector developed by Russian scientists. Image Credit: NASA/JPL-Caltech/Russian Space Research Institute.

Fig. 31 Time distribution of backscattered epithermal neutrons (red curve) and back-diffused thermal neutrons (blue curve). Blue dots represent hydrogen atoms while the other colors represent other common chemical elements in the soil or rock. Figure reproduced based on information from NASA/JPL-Caltech/Russian Space Research Institute.

About a month later, NASA made the surprising announcement that the Mars Reconnaissance Orbiter (<https://www.jpl.nasa.gov/missions/mars-reconnaissance-orbiter-mro/>), launched August 12, 2005, had discovered signatures of hydrated minerals streaking down canyon hill sides and changing “colour” between warm and cold seasons (Carey, 2015). Could this be signs of flowing water?

At the time of writing this article (September 2020), the Discovery rover is still in operation and has traversed a distance of 14.12 miles (22.72 km). Each year DAN carries out around 120 measurements. About 1,300,000 neutron pulses of the neutron generator have been spent on this mission. This neutron-based method has proven beyond doubt that hydrogen-containing water-related molecules exist in the soil and rock.

Glossary

Adatoms Atoms that lie on a material's surface, as opposed to a surface vacancy defect.

Case hardening Process of hardening the surface of a material while keeping the core soft. This is done by implanting atoms that occupy interstitial sites. Also known as surface hardening.

CMOS Complementary metal oxide semiconductor. It is a metal-oxide-semiconductor field-effect transistor (MOSFET) fabrication process. It consists of complementary and symmetrical pairs of p-type and n-type MOSFETs for logic functions. These are connected to a common secondary voltage such that the pair operates in opposite (complementary) fashion. Thus, when one semiconductor is turned on, the other is turned off, and vice versa.

CVD Chemical vapor deposition. This is a vacuum deposition method used most often by the semiconductor industry to produce high quality, high-performance, thin films. The process makes use of compounds that evaporate when heated under vacuum or react from a gas mixture that flows over a solid substrate film that is heated. Evaporated compounds or gas mixtures decompose or react on the substrate surface forming a ceramic or metal thin film. The process is also adapted for growing organic compound thin films and polymer thin films. The film thickness can vary from a single-atom layer to micrometer thick films. Alternating layers of different chemical composition can be grown into superlattices.

DLC Diamond-like carbon. It is an amorphous carbon material with mostly sp^3 bonding and tetrahedral symmetry that exhibits many of the desirable properties of the diamond material such as hardness, wear resistance, and electrical resistivity.

EBL Electron-beam lithography, the direct writing lithographic process that uses a focused, high-energy beam of electrons (e-beam) to form patterns by material modification, deposition, or removal.

Electronegativity Electronegativity is a measure of the tendency of an atom to attract a bonding pair of electrons. The Pauling scale is the most commonly used. This property is affected by the atomic number of the atom and its radius.

EUV Extreme ultraviolet radiation. It consists of the portion of the electromagnetic spectrum with wavelengths in the range of 10 nanometers (nm) to 124 nm, therefore having photons with energies of 124 electron-volts (eV) down to 10 eV, respectively. EUV is used in the photolithography process.

FTIR Fourier-transform infrared spectroscopy. This type of spectroscopy excites the vibrational motion and sometimes rotational-vibrational motion of molecules in a gas, liquid and solid phase by means of an infrared radiation. The infrared region of the electromagnetic spectrum comprises the wavelengths of 700 nm to 1 mm. Part of the infrared radiation is transmitted by molecules, and another part is absorbed at specific wavelengths. The absorbed infrared is characteristic of particular chemical bonds between atoms forming a polar compound. Rather than exciting a single wavelength, this technique uses a Michelson interferometer, and all the infrared waves reflected back to the detector are analyzed by Fourier Transform. This allows for all infrared wavelengths to be scanned and computer analyzed within seconds and in a single measurement.

Graphene Allotropic form of carbon that consists of a single layer of carbon atoms arranged in a two-dimensional honeycomb lattice.

HDPE High-density polyethylene. In contrast to LDPE, the HDPE has high degree of crosslinking and is extruded using low pressure in the range of 6–7 atmospheres (atm) and low temperature in the range of 333–343 K.

IBAD Ion beam assisted deposition is a technique that combines ion implantation with simultaneous sputtering or another physical vapor deposition technique. It provides independent control of parameters, i.e., ion energy, temperature and arrival rate of atomic species during deposition. This technique is especially useful for thin films as it creates a gradual transition between the substrate material and the deposited film, resulting in films with a much more durable bond to the substrate.

LDPE Low-density polyethylene. This form of PE has low degree of crosslinking and it is extruded using pressures of 1000–5000 atm and a high temperature of 520 K.

Magnetron sputtering A high-rate vacuum coating technique that uses a specially formed magnetic field applied to a diode sputtering target.

MTJ Magnetic tunnel junction. It is a type of spintronic device that consists of two ferromagnetic layers separated by a thin insulating film. When the insulating film thickness is the order of a few nanometers, electrons can tunnel from one ferromagnet into the other. For magnetic layers having opposite large spin polarizations, large resistance changes occur through the junction due with tunneling of electrons with opposite spin polarization taking place. Consequently, the moments of the magnetic layers can be switched from a parallel to an anti-parallel alignment.

Photolithography This is a process used in microfabrication or formation of micropatterns on a thin film or the bulk of a substrate. It uses light to transfer a geometric pattern from a photomask to a photosensitive chemical photoresist on the substrate. The dimensions of the patterns match the wavelength of the light used, or that of the photomask.

Photoresist Light-sensitive material.

PII Plasma ion implantation, also known as pulsed-plasma doping. This is a technique for surface modification. Accelerated ions from a plasma are extracted by an externally applied high voltage and targeting them into a target substrate or electrode with a sample wafer placed over it. The high energy ions are, thus, implanted into the sample wafer.

Radiolysis Dissociation of molecules by ionizing radiation.

Sputtering Ejection of surface atoms and microscopic particles from a material upon bombardment with high energy particles from a plasma or gas.

Steric hindrance Slowing of a chemical reaction due to steric bulk and that relates to the spatial arrangement of atoms in molecules. The steric bulk is the relative volume of chemical functional groups neighboring the reactive site of a molecule or polymer and that are connected along its principal chain of carbon atoms.

SWNT Single-walled carbon nanotube. This carbon allotrope can be idealized as consisting of a single graphene sheet cutout that is rolled into a tube form along one of the Bravais lattice directions of the hexagonal system to form a hollow tube. The tube diameter, length and chirality affect the nanotube properties.

Thermoplastic, thermoset and thermo-responsive polymer Thermoplastic polymers soften when heated and harden when cooled reversibly, whereas thermoset polymers harden irreversibly upon heating as a consequence of crosslinking. Thermo-responsive polymers are a class of stimuli-responsive materials that exhibit conformational changes in response to temperature stimuli, especially near body temperature. These have unique sol-gel transition properties above a certain temperature.

UHMWPE Ultra-high molecular weight polyethylene is a subset of the thermoplastic polyethylene. This material is also known as high-modulus polyethylene (HMPE). It has extremely long chains, with a molecular mass usually between 3.5 and 7.5 MDa (1 Da = 1 amu or atomic mass unit; MDa = million Da).

YSZ Yttria stabilized zirconia is a ceramic material of zirconium oxide (ZrO_2) cubic crystal phase, also known as zirconia. The cubic crystal phase is only stable at temperature above 2370 °C. It then converts to the tetragonal phase below this temperature, and finally to the monoclinic phase below 1173 °C. The tetragonal to monoclinic transition is accompanied by a 5% volume change of the crystal lattice and it is stabilized by doping with yttrium oxide (Y_2O_3), or yttria. In order to stabilize the cubic crystal lattice, yttria is added since Y^{3+} has an ionic radius that is 17% larger than that of Zr^{4+} . Other materials associated with YSZ are calcia (CaO), magnesia (MgO), ceria (CeO_2), and alumina (Al_2O_3) stabilized zirconias.

Introduction

The irradiation of materials offers the possibility to tailor structures at wavelengths far below those of visible and ultraviolet radiation (Trautmann, 1999). The wavelengths of high energy electrons, neutrons, X-rays and gamma photons can match interatomic distances in solids. This property allows for the removal of single atoms from a crystalline lattice position, breaking and forming new chemical bonds, and consequently generating defects, and even nanosized patterns (Nayfeh, 2018).

Radiation is of major importance for developing commercial polymer materials. Polymers are composed primarily of chains of carbon atoms that are bonded to hydrogen. They may also contain functional groups of non-metal elements such as oxygen, nitrogen, silicon, sulfur, phosphorus, fluorine and chlorine. Polymers are classified as low temperature materials (Rösler et al., 2007; Li et al., 2012).

Electrons and gamma photons have enough energy to break covalent chemical bonds between carbon atoms or between carbon with hydrogen. Breaking these bonds leads to carbon atoms having an unpaired electron, a chemical species known as a free-radical. The rupture of a bond between two carbon atoms is a process known as *chain scission*. The generated radicals are highly reactive in nature and can react to form new chemical bonds. When carbon radicals react with other radical or ion species, such as oxygen and nitrogen present in the atmosphere, the reaction leads to shorter polymer chains and the formation of new chemical functional groups.

When carbon radicals form without breaking the polymer chain, the carbon radicals in one polymer chain can quickly form new bonds with other carbon atoms from neighboring polymer chains. This process is known as *crosslinking*, and it is responsible for the increase in molecular weight of polymers and their viscosity, mechanical and thermal stability (Farhataziz and Rodgers, 1987; Cleland et al., 2003). Crosslinking is also of major importance for the manufacturing of elastomers, tires, heat shrink plastics, to name a few. Chain scission and crosslinking are both used for the manufacturing of porous track-etched membranes, for the recycling of plastics, and for the blending of otherwise immiscible polymer phases. Both processes also find application in processing wood pulp into viscose fibers for clothing, and for manufacturing of wood-plastic products that are water proof (Clough, 2001; Cleland et al., 2003).

Metals and ceramics are of major technological importance and are classified as high temperature materials because they both have melting points greater than 500 °C. Metals are often formed by a single element or by combinations of different metal elements forming alloys and intermetallic compounds. In metals, lattice positions are occupied by individual atoms. The relative atomic position of each atoms with respect to the others is dictated by the atomic radius. This packing is the most efficient possible for a given metal. Typical lattice defects include vacancies, surface adatoms, and dislocation lines (Rösler et al., 2007). Irradiation of metals displaces atoms from their positions and atoms diffuse to occupy vacancies. To cause the displacement of atoms, the energy of the incident particles must exceed the binding energy of the atoms in the target (Zinkle and Matsukawa, 2004; Azevedo, 2011). Roughly 90% of all dislocated atoms diffuse to occupy vacancies left by other atoms in the lattice (Zinkle and Matsukawa, 2004). Defects are engineered in this way.

Doping of metals and ceramics is another important area of study. This technique is based on the use of ions in a plasma that are accelerated within an electric field and directed toward target metals. These accelerated ions penetrate the crystal lattice of the target material and diffuse to occupy specific positions. Some commercial examples include the use of nitrogen to harden steels, a process known as case hardening (Ensinger, 2006).

Ceramic materials have at least one element from the main group of metals, or a transition metal element paired with a non-metal element. These include metal oxides and sulfides, carbides and nitrides. Differences in electronegativity between the elements dictate if the ceramics will be ionic or covalent. Atoms in covalent ceramics share pairs of valence electrons, whereas the forces between charged elements are primarily electrostatic in ionic ceramics. Ionic ceramics assume crystal structures that most effectively balance the repulsive (between ions of the same charge) and attractive electrostatic forces (between ions of opposed charges). Ceramic materials also include those formed between a semimetal and a non-metal and these are often covalent. The spatial arrangement of atoms is determined by the elements forming the bond and number of bonds (Rösler et al., 2007). Carbon materials, i.e., diamond-like carbon (DLC) (Delplancke-Ogletree, 2006), graphene, graphite, fullerene and carbon nanotubes (Geim and Novoselov, 2007) are often treated as ceramics although these have only carbon atoms in the structure (Rösler et al., 2007).

Most commercial developments and ongoing research efforts are focused on high energy electrons for designing ceramics with unique properties. When high energy electrons hit a solid surface, only a fraction of energy will be transferred to a target atom. The transferred energy often matches the binding energies of atoms in solids, resulting in ionization of atoms and breaking of chemical bonds (Krashennnikov and Banhart, 2007). Besides allowing for the selective etching of surface atoms and formation of grids and patterns (Nayfeh, 2018), the removal of ions or of neutral atoms from an ionic or covalent ceramic material leads to a vacancy that is associated to a charge imbalance. This is what occurs in yttria stabilized zirconia (YSZ), an important industrial ceramic. These imbalances are often used for increased oxygen ion-conduction in YSZ, making these more active catalysts, electrodes for high temperature fuel cells and oxygen sensors (Dow et al., 1996; Resini et al., 2008).

Moreover, nuclear reactions can take place and lead to the transmutation of individual atoms in a crystal lattice. An example is that of silicon (Si), an intrinsic semiconducting ceramic. The ^{30}Si isotope in Si wafers transforms into phosphorus (P), yielding P-doped Si. (Janus and Malmros, 1976). This localized transmutation can take place at positions within the bulk of the Si wafer. This doping changes the electrical properties of Si and make it suitable for uses in energy storage and conversion devices such as solar cells and Lithium-ion batteries (Haas and Schnöller, 1976; von Ammon, 1992; Ozanam and Rosso, 2016).

These examples are presented in this article, along with some of the relevant theoretical background to enable an understanding of these processes. This article begins by covering polymers that are classified as low-temperature materials. It then proceeds to metals ceramics, composites, and nanomaterials. The use of radiation for the manufacturing of semiconductors, and for the quality control of sheet products and packaging industry are also covered. The use of irradiation for food, pharmaceutical and cosmetics industries are briefly mentioned, as these are covered in detail in other chapters. Some specific techniques and instruments used for gamma, heavy ions and focused electron beams are also described where appropriate.

Polymers (low temperature materials)

The number of new products that come into general commerce on an almost daily basis owe a good deal of their creation and development to radiation processes. Several of these products are highlighted in bold print, to help the reader focus on topics of most personal interest.

Hydrocarbon-based materials are classified as low temperature materials and are often referred to as soft materials. These include low molecular weight compounds, such as most liquid crystals, low and high-molecular weight polymers and resins, and biological tissues. These compounds undergo large deformation and various morphological changes in response to environmental stimuli (mechanical forces, temperature, humidity, pH, electric fields and van der Waals interactions). Polymers are selected for low temperature applications, being limited to temperatures below melting or decomposition (Li et al., 2012). These temperatures are often less than 500 °C.

Polymers, polymer hydrogels and polymer-matrix composites are the most important groups of commercial materials. The radiation dose (Dewji et al., 2021) of 10 kGy (1 Mrad) will increase the temperature of a polymer by 7 °C, and only $\sim 10^{-5}$ fraction of all chemical bonds will be broken. This is enough to reduce the average molecular weight of polymers from 10^6 down to 0.3×10^6 Da, leading to a drastic change in mechanical strength (Farhataziz and Rodgers, 1987). The polymer chain structure dictates whether it crosslinks (forming covalent bonds between neighboring polymer chains) or scissions (where the covalent bond between two carbon atoms is broken along the linear segment of the polymer chain). Polymers with sterically hindered chains undergo scission, whereas those with exposed carbon atoms along the main chain undergo crosslinking (Farhataziz and Rodgers, 1987). The fraction of broken bonds and the reactions that follow constitute the basis of radiation processing of polymers. Table 1 lists polymers that undergo crosslinking or chain scission due to steric hindrance (Cleland et al., 2003).

The specific energy (SE) required for polymers to undergo chemical reactions in units of kJ/kg is equal to the absorbed dose (D) in kGy (kiloGrays)

$$SE = N_A \times (100/G) \times q_0 = 6.022 \times 10^{23} \times (100/G) \times (1.602 \times 10^{-19}/10^3)$$

$$SE = 9.65 \times 10^6/G, [\text{kJ/mol}]$$

where N_A is Avogadro's number and q_0 the elemental electrostatic charge. The G-value is defined as the number of events (cross-linking or chain scission reactions) per 100 eV of absorbed energy. An expression for dose is obtained (Cleland et al., 2003) as a function of $10^3/\text{MW}$, in units of mol/kg, and where MW (g/mol) is the polymer molecular weight:

$$D = 9.65 \times 10^6/(\text{MW} \times G), [\text{kGy}]$$

Table 2 lists G values for most common polymers (Cleland et al., 2003).

Often times, the scission of main chain chemical bonds leads to the formation of intermediate reactive species that induce cross-linking of chains. For 1 in every 10^5 specific bonds that are broken by irradiation, the viscoelastic, mechanical and thermal properties of polymers can change drastically (Farhataziz and Rodgers, 1987). This is observed for the crosslinking of waste polyethylene/nitrile butadiene rubber (PE/NBR) with a gamma-radiation dose of 50 kGy, for which the thermal stability improves by means of covalently binding both polymers (Aly, 2016). For processing, the irradiation of Teflon reduces the particle size and molecular weight, allowing its incorporation into coatings, inks, etc. Also, broadening of the molecular weight distribution of polypropylene (PP) to enhance melt flow characteristics allows for easier molding (Clough, 2001).

Polymer radiation-processing technologies are dedicated to cross-linking of plastics and rubbers, curing of coatings and inks, heat-shrink products, fiber-matrix composites, chain-scission for processing control, surface modification, grafting, hydrogels, sterilization, natural product enhancement, plastics recycling, ceramic precursors, track-etched membranes and photoresist coatings in lithography for microdevice production. Gamma and e-beam sources, as well as ion beams (heavy ions, light ions, highly focused microscopic beams and high-intensity pulses), soft X-rays and e-beams undergo scattering to generate nanosized patterns (Farhataziz and Rodgers, 1987; Clough, 2001; Singh, 2001). Nanomaterials have at least one of their dimensions under 100 nm in size and have their properties (mechanical, electrical, thermal) impacted by size (Pokropivny et al., 2007).

Extreme ultra-violet (EUV) photons have wavelengths greater than 10 nm and do not allow for precise manipulation of materials approaching the molecular and atomic levels. Consequently, methods such as EUV lithography and photolithography, are limited by wavelength for nanomaterials design and nanopatterning. This limitation is overcome by gamma, X-rays, heavy ions

Table 1 Common commercial polymers and radiation reaction characteristic.

<i>Mainly crosslinking</i>	<i>Mainly scission</i>
Polyethylene	Polyisobutylene
Polyacrylates	Polymethacrylates
Polyvinyl chloride	Polymethylstyrene
Polysiloxanes	Polymethacrylamides
Polyamides	Polyvinylidene chloride
Polystyrene	Polytetrafluoroethylene
Polyacrylamides	Polypropylene ether
Ethylene vinylacetate	Cellulose

and e-beams (Trautmann, 1999). Radiation emitting instruments exist to control patterning at the nanometer scale. Selected methods are described in following sections, namely e-beam lithography and ion-implantation based on sputtering and magnetron sputtering. This process is also commonly used for metals and ceramics.

Crosslinking and chain scission

Crosslinking

Crosslinking by radiation is a widely used technology in industry for producing crosslinked wire insulation, heat-shrink products such as food wrap and tubing for electrical connections, and self-resetting polymer-based electrical fuses and self-regulating heat tape. Curing of coatings and inks is also an established use of radiation in the production of tubing, pipes and automobile tires, as well as fiber–matrix composites (Ueno, 1990; Gehring and Zyball, 1995; Clough, 2001). These include polyethylene terephthalate (PET) and Nylon (Ueno, 1990), polyethylene (PE) containing blends (Singh, 2001) and fluorinated polymers (Lyons, 1995). Crosslinked polymers maintain their shape, and have increased thermochemical stability, tensile and flexural strength, and better resistance to stress cracking and to creep (Nielsen, 1969).

In his seminal work, Charlesby observed that polyethylene formed an insoluble gel when exposed to reactor radiation. This contradicted the thought that crosslinking was only possible through the addition of chemical agents to polymers having suitable functional groups (Charlesby, 2016). A primary example of the latter is the vulcanization of rubber that proceeds through sulfur addition to double bonds along the principal chain of rubber. In contrast to the energy intensive thermal vulcanization, a minimum gamma radiation dose of 12 kGy is sufficient to vulcanize natural rubber latex in the presence of *n*-butyl acrylate (*n*-BA) (Haque et al., 1996). This offers substantial environmental and economic advantages over thermal and chemical processing of polymers and elastomers. Commercially used elastomers that are crosslinked using radiation include silicone (Basfar, 1997), styrene-butadiene block copolymers (Dakin, 1995), ethylene propylene diene monomer (EPDM) (Banik and Bhowmick, 2000; Nuinu et al., 2012), polybutylene terephthalate (Gehring, 2000), nitrile rubber, latex (Minoura and Asao, 1961), and polymethylmethacrylate/acrylonitrile-butadiene rubber (PMMA/ABN) blends (Cangialosi et al., 2001).

Crosslinking of polymeric foams include gamma irradiated polyethylene (Cardoso et al., 1998) and polypropylene blends (Tokuda and Kemmotsu, 1995), and e-beam (doses of 20–200 kGy) irradiated natural rubber-thermoplastic blends (Ghazali et al., 1999) and polyvinylchloride (PVC) (Sharma et al., 1995), used for heat insulation, automotive cushions, sporting goods and buoyance devices.

E-beam processing has been found to facilitate the blending of phase-segregated polymer phases into copolymers via crosslinking, as in between ethylene propylene/polyethylene (EP/PE). PE is hard plastic and susceptible to cracks during processing of wire insulation and of elastomeric automotive parts, but blending renders it flexibility and creep resistance (Spenadel, 1979). The processability of PP with EPDM forming PP/EPDM blends (van Gisbergen et al., 1989a) and of polystyrene/low density polyethylene (PS/LDPE) blends (van Gisbergen and Meijer, 1991) using e-beams allows for control over rheological properties. The e-beam induced crosslinking allows for fixation of the blended phases, whereas the chain scission of some non-crosslinked PP or LDPE leads to reduced viscosity and increased flowability for injection molding processing. Resulting polymers exhibit defined morphology for the blends and increased impact strength and elongation than low molecular weight PP with similar viscosity (van Gisbergen et al., 1989a).

Increasing temperature increases thermal vibrations in polymer chains. Flexible polymer chains adopt different configurations and move more freely. The entanglements between linear polymer chains disappear and reform along different points between neighboring chains. The number and lifetime of entanglements depend on temperature. These entanglements act momentarily as crosslinks. The minimum radiation dose required to induce covalent crosslinking between chains, and consequently gelation, depends on the molecular weight average and the viscosity. Increasing molecular weight leads to higher viscosity values, whereas at high temperature, the viscosity drops as a result of the decrease in entanglements between chains (Farhataziz and Rodgers, 1987). This allows crosslinking of fluorinated polymers to take place above their melting points under vacuum or inert atmospheres. When irradiated at ambient conditions, chain scission prevails and oxidation takes place, allowing PTFE to be used as an additive to **ink compositions** (Sun et al., 1994; Oshima et al., 1995; Lappan et al., 2000; Seguchi, 2000). The fact that high-molecular weight PTFE resin does not flow even above its melting point and that it is insoluble in any solvent make its processing difficult. This is facilitated by the use of ionizing radiation. A popular commercial name of this polymer is **Teflon** (DuPont). PTFE is commonly used as a **nonstick coating for cookware, in the manufacture of semiconductors and medical devices, as coatings for bulk chemical containers, eyeglasses, and shaver blades, and as an inert ingredient of pesticides.**

Heat shrink products rely on the ability to crosslink a polymer using e-beams while retaining any crystalline domain during the process, a process that is not often possible by chemical methods. After crosslinking, the polymer is heated above its melting point and stretched to about twice the original length and then cooled in a stretched state. The crosslinking prevents the material from flowing. The elongation is retained until the polymer is again heated, at which point the crosslinks will bring the polymer chains back to the original size (Cook, 1990). This is common for PE used in **food wraps** (Datta et al., 1997) and in **electrical tubing insulation** (Wenyuan et al., 1995).

Curing of inks, abrasion protective and diffusion barrier coatings, and adhesives is also achieved using low energy e-beam (Ohta et al., 1990; Thalacker, 1990; Holl, 1995). The penetration depth of the e-beam depends on dose and monomer polymerization can be monitored using Fourier transform infrared spectroscopy (FTIR), as demonstrated for acrylate monomer polymerization (Patacz et al., 2000). In particular, **oxygen diffusion barriers are of interest to food packaging industry.** Examples include the e-beam curing of methacrylate gelatin (Scherzer, 1997) and the ethylene vinyl alcohol (EVOH) and acrylonitrile that are compatible with LDPE films (Rangwalla and Nablo, 1993). Compared to ultraviolet (UV) curing, e-beam irradiation has advantages including energy savings, curing time, crosslinking of deeply pigmented dyes, and solvent-free systems (Läuppi, 1990). Nonetheless, the curing process can be combined with UV irradiation, demonstrating e-beam versatility toward combination of polymers that crosslink under e-beam or that require UV (Nablo, 1990).

Radiation has been applied to coating wood for **wood-plastic composites (WPC), wood-fiber reinforced plastics, and laminated WPCs** (Clough, 2001). Production of WPCs uses acrylates, styrene, vinyl acetate, and other monomers that crosslink (Khan et al., 1993). These are impregnated into wood that has 80% accessible porosity. The process is then followed by polymerization using gamma or e-beam. Composite materials have increased mechanical properties (Palm et al., 2015), including hardness (Solpan and Güven, 1999), tensile (Garnett and Ng, 1996) and flexural strength (Palm et al., 2016). Commercial products include **flooring and table tops, and laminated wood panels.**

Chain scission

The opposite of cross-linking is chain scission, which is the degradation of the main chain of a polymer via breaking covalent bonds. Many polymers undergo main-chain scission and experience degradation of mechanical properties. Side chain scission has only a minor impact in mechanical properties of polymers (Farhataziz and Rodgers, 1987). Chain scission may also be referred to as degradation, since polymer chains undergo fragmentation or decrease in the degree of polymerization (Clough, 2001; Cleland et al., 2003).

Polymers such as PP are irradiated with e-beams for inducing chain scission during its processing into fibers. Pristine PP has low melt strength, and irradiation leads to chain scission and long-chain polymer branching (Lugão et al., 2000). Chain scission prevails and yields double bonds between carbon atoms. The double bonds contain carbon atoms with sp^2 electronic hybridization. The latter increases electronic density over the C atoms, which are also less hindered due to the planar configuration adopted by the C atoms, as compared to C atoms forming single bonds and having tetrahedral configuration from the sp^3 hybridization (Ouellette and Rawn, 2018). These react and result in branching of chains. This process is also known as “viz-breaking” and it results in a melt with increased strength and processability (Clough, 2001). The improved rheological properties of the irradiated PP melt allow for melt mold and for fiber processing options (Lugão et al., 2000; Cleland et al., 2003).

E-beam irradiation has been used to induce the scission process to partially break cellulose from wood pulp into **viscose**. The viscose is then processed into **staple fiber, filament, cord, film, packaging, and non-edible sausage casings.** These materials are widely used in the **clothing, drapery, hygiene, automobile, food, and packaging industries.** E-beam irradiation eliminates hazardous chemicals and thermal energy required by conventional processing of wood pulp (Stepanik et al., 2000).

Functional polymers

The presence of air can lead to the oxidation of polymers at scission and introducing new functional groups. Cotton-cellulose is oxidized during fragmentation using gamma-irradiation with 15–100 kGy dose. The degree of polymerization decreases from 1200 down to 330, and carbonyl groups appear as a consequence of oxidation. Lower doses yield **fibers with enhanced crease resistance** (Takács et al., 1999).

E-beam irradiation of polytetrafluoroethylene (PTFE), copolymers of tetrafluoroethylene with hexafluoropropylene (FEP), and perfluoropropylvinylether (PFA) result in carbonyl groups forming. These groups quickly convert to carboxylic acid groups from contact with moisture in air (Lunkwitz et al., 2000). These oxidized fluoropolymers have better compatibility with polar compounds, make it easier to blend them, such as using PTFE as **ink additive**, for example.

The inert PE has been blended with other polymers and resins such as polyamide using chain scission and oxidation of PE by gamma-irradiation in the presence of air. The polymers were then blended with polyamide, resulting in materials with increased tensile strength (Valenza et al., 1993). The use of oxidizing conditions and N^+ ion beam also led to PE films having better adhesive properties, and binding with increased strength to **epoxy adhesive films** (Mesyats et al., 1996).

Ion beam irradiation of different polymers has also been reported to improve polymer metallization with Al and Cu. Besides improving interaction with the deposited metals, enhanced polymer crosslinking provides a diffusion barrier to the metals. These composites are of interest for **optoelectronics and microelectronic devices, and for electromagnetic radiation shielding** (Bertrand et al., 1997; Kupfer and Wolf, 2000; Rück, 2000).

Graft copolymerization with different monomers is a method for modifying the surface of polymer chains. Grafting can be promoted by e-beam, gamma and ion irradiation (Garnett, 1979). PTFE has been modified by styrene, acrylic acid, 4-vinylpyridine and *N*-vinylpyrrolidone to make **permelective membranes** (or ion-exchange membranes) having acid and basic surface groups (Chapiro, 1977). Grafting is a method used to modify polymer biocompatibility, make them suitable for artificial organs, soft and hard tissue substitutes, and diagnostic or therapeutic instruments and devices (Hoffman, 1977).

Grafting has also been used to modify PE fibers using gamma-radiation and copolymerized with amidoxime for **extraction of uranyl ions from seawater**. The uptake in batch experiments reached 3.3 mg of Uranium/g of sorbent after 8 weeks of contact with seawater. The expected cost of this process using the sorbent developed by Oak Ridge National Laboratory was of USD610/kg of Uranium (Kim et al., 2014). Advantages of this extraction method include the lower energy input required for passive mining compared to mining uranium ores, and the much greater amount of U present in seawater compared to terrestrial mines (Conca, 2016).

Fiber-matrix composites

Fibers are dispersed in a polymer matrix and processed into sheets that are rolled, stacked and molded for different applications. The matrix plays a protective role and provides a medium in which the fibers are oriented as to obtain isotropic or anisotropic properties. The strength of fiber-matrix composites depends on fiber length, relative orientation and in the strength of the interaction between fiber and polymer matrix.

Examples of e-beam crosslinking of fiber-matrix composites include epoxy resins with carbon fibers (Lopata et al., 1999) and with lignocellulosic fibers (Güven et al., 2016). The carbon and wood fiber-matrix composites find **structural applications for aerospace** (Saunders et al., 2000), **maritime** (Chappas et al., 1999), **automotive parts, and sporting goods** for their lightweight and high mechanical strength (Singh et al., 1996; Güven et al., 2016). Polymer coatings also make cellulosic fibers less hydrophilic, thus extending the lifetime use of these environmentally friendly and inexpensive composites in **furniture and laminated wood panels** (Güven et al., 2016). Overall, e-beam irradiation of composites provides reduced ambient temperature curing, reduced curing times, reduced volatile emissions, better material handling, and reduced costs over conventional thermal processing of composites (Singh et al., 1996; Chappas et al., 1999).

Track-etched membranes

Polymer track-etched membranes are porous polymer films formed from irradiation with high energy ions and subsequent chemical etching of damaged polymer regions by means of oxidizing agents. Track-etched membranes are commercially available and manufactured by companies such as Nuclepore™, Oxyphen GMBH, and Sterlitech Corporation.

Porous membranes having pore widths below 100 nm and in micron size range find many industrial applications including **purification and separation of gases and liquids, water filtration and desalination, separations of petrochemical products, processing of food and beverages, purification of biological and pharmaceutical compounds**. Control over the pore dimensions is of major importance for separations, as these are often dictated by size exclusion, as illustrated in Fig. 1A, and by hydrophilic properties of the pores (Virk and Kaur, 1998; Reber et al., 1999; Shumskaya et al., 2019). Pore size, shape and surface chemistry is also of major importance for the development of electrochemical biosensors. While selective binding of target elements, chemical compounds, DNA, proteins and other biomolecules depend on surface functional groups present in the membrane electrodes, the electrolyte accessibility and diffusion resistivity that is measured by electrochemical methods are a direct consequence of the membrane pore size and shape (Pérez-Mitta et al., 2017; Kaya and Keçeci, 2020).

Most chemical processes require multiple steps and the use of sacrificial templates to form pores, or use of polymer binders for inorganic porous materials prepared in multiple steps (Yang et al., 2011). Thus, track-etched membranes present several advantages over traditional membranes including the elimination of sacrificial templates, reduced number of steps to prepare, and a broad range of polymer products that can be irradiated. Moreover, the density of pores in these track-etched membranes can be regulated by the ion fluence, with higher fluences leading to greater densities of pores per unit area (Kaya and Keçeci, 2020).

For instance, irradiation of thin polymer films such as PET with heavy ions, i.e., Ar^+ , Kr^+ , Xe^+ , Au^+ and U^+ , and often having energies approaching 12 MeV, create micron and nanosized pores with uniform geometry. The pores form from extended chain

Fig. 1 (A) Size exclusion of molecules in the open (a, b) and closed (c, d) state of a responsive pore. In the closed state, only small pores formed between entangled polymer chains remain open and are accessible to small ions and molecules; larger biomolecules and polymer encapsulated compounds are excluded by size. In the open state, the polymer walls become denser, and larger pores form. This type of smart polymer material prepared using irradiation methods has been reported for both track-etched membranes and hydrogels sharing similar composition. (B) These are cylindrical pores in a polyimide track-etched membrane. From (A) Reber N, Omichi H, Spohr R, Wolf A, and Yoshida M (1999) Closure characteristic of thermally responsive ion track membranes. *Nuclear Instruments and Methods in Physics Research Section B: Beam Interactions with Materials and Atoms* 151 (1): 146–153. (B) Trautmann C (1999) Modifications induced by swift heavy ions. *Bulletin of Materials Science* 22(3): 679–686.

scission and oxidation reactions from chemical agents (NaOH solution) along the ion path. Competing crosslinking reactions help limit the scission and oxidation reactions and define the pores size at ranges up to 100 nm (Apel et al., 1998).

The scanning electron microscopy (SEM) image in Fig. 1B depicts a polymer track-etched membrane film cast on polyamide (Trautmann, 1999). Similarly, other polymers such as polyimide (PI) and poly(ethylene naphthalate) (PEN) with pores of 100 nm and less were prepared after film stacks were irradiated with Kr^+ , Xe^+ and Bi^+ ions with energy in the order of 10 MeV and chemical etching.

Regarding geometry, the pores of the track-etched membranes can be cylindrical, conical, bullet-like, hourglass (double-conical), and cigar-shaped, with the shape being controlled by the chemical etching method (Kaya and Keçeci, 2020). The cylindrical shape, for example, is evidenced by the shape of nanowires grown by electrodeposition within the nanopores of bisphenol-A polycarbonate (BPC) irradiated with Ar^{9+} ions (5 MeV/amu of energy) and etched using NaOH and a surfactant solution. After the BPC films were dissolved in dichloromethane, the nanowires had rod-like shape and their diameters were comparable to the widths of the BPC channels, 20–100 nm. As with other track-etched membranes, the pore widths were controlled by irradiation time (Ferain and Legras, 1997).

Membranes with ion channels mimicking those found in biological systems are of interest to the development of ionic sensors (Pasternak et al., 1995; Pérez-Mitta et al., 2017). This has been demonstrated for narrow pore polyethylene terephthalate (PETP) membranes. After etching to open the membrane pores, polymethylvinylpyridine (PMVP) was subsequently grafted on the pore surfaces to develop a functional material. The properties included rapid switching, selectivity between cations and anions, and modulation by H^+ and divalent Zn^{2+} and Ca^{2+} cations.

Track-etched membranes that are thermo-responsive are classified as smart-materials and are of major interest for encapsulating drugs for targeted therapies and for tissue engineering (Sponchioni et al., 2019). Above a threshold temperature, these materials lose water and consequently the polymer walls shrink. In the shrunk state, the pores open up. Below this threshold temperature, the polymer re-hydrates, thus swelling the polymer walls and closing the pores, as illustrated in Fig. 1A. An example of applications for these polymers in drug-delivery are cancer therapies. In these, encapsulated drugs used for killing cancer cells are absorbed exclusively by cancer cells. Since temperature and pH conditions in the blood plasma and inside cells differ, the drugs are then released inside the cancer cells, and healthy cells are preserved (Sponchioni et al., 2019).

In existing chemotherapy, these drugs are directly injected in the blood stream and circulate in the entire body, killing both cancer and healthy cells. Given the pore dimensions of track-etched membranes as poly-diethylene glycol-bis-allyl carbonate (CR-39) and a thermo-responsive gel acryloyl-L-proline methyl ester (A-ProOMe) (Yoshida et al., 1997), and of poly-N-isopropylacrylamide (Reber et al., 1999) that can reach 0.3 and 3.5 μm , respectively, small drugs, polyethylene glycol (PEG) encapsulated drugs, and even proteins can be safely delivered to target cells and organs. This is achieved with small temperature changes in a very narrow range around 30 °C (Yoshida et al., 1997; Reber et al., 1999).

Hydrogels

Hydrogels are polymer materials that have the ability to swell in water and retain 10–1000 times of their original weight or volume of water and water-based fluids within their structure. Given the highly crosslinked polymer network forming the

hydrogels, these materials do not dissolve in water. Hydrogels can be of natural or synthetic origin. Similar to other polymers, the hydrogel network can be formed by radiation induced crosslinking. Some of the most commonly used polymers forming hydrogels include polyvinyl alcohol (PVA), polyacrylamide (PAAm), polyvinyl-pyrrolidone (PVP), polyethylene oxide (PEO) and methyl cellulose (MC). Hydrogel technologies may be applied to **hygienic products, diapers, contact lenses, agriculture, drug delivery systems, sealing, coal dewatering, artificial snow, food additives and packaging, pharmaceuticals, tissue engineering and regenerative medicines, diagnostics, wound dressing, separation of biomolecules or cells and barrier materials to regulate biological adhesions, and biosensors** (Laftah et al., 2011; Peppas et al., 2012; Ahmed, 2015; Ullah et al., 2015).

Gamma and e-beam irradiation have been used to initiate the polymerization in aqueous solution for preparing hydrogels of unsaturated compounds. The irradiation results in the formation of radicals on the polymer chains. The parallel process is the radiolysis of water molecules which yield hydroxyl radicals that also attack the polymer chains resulting in the formation of macro-radicals. Recombination of the macro-radicals on different chains leads to forming of covalent bonds and finally a cross-linked structure (Farhatziz and Rodgers, 1987).

Examples of polymers crosslinked by gamma irradiation include the pH-sensitive PEO hydrogels grafted with acrylic acid (AAc) (Nho et al., 2004), copolymers of polyethylene glycol methacrylate and acrylic acid (Park et al., 2004a) and PVA networks grafted with AAc or methacrylic acid (Park et al., 2004b), the thermo-responsive copolymers of 2-hydroxyethyl methacrylate (HEMA) and itaconic acid (IA) (Tomić et al., 2007), and the superabsorbent nanocomposite of poly[acrylamide-co-(acrylic acid)]/montmorillonite (Luo et al., 2005). The major advantage of the radiation initiation over the chemical initiation is the production of relatively pure hydrogels and that are free of chemical radical polymerization initiators (Laftah et al., 2011; Ahmed, 2015; Ullah et al., 2015).

Plastic recycling

Plastic waste is a global problem impacting land and oceans. The USA is the world's leading nation in plastic waste generation, with an estimated amount of 42.0Mt produced in 2016. Out of this figure, up to 0.41 Mt were illegally dumped and 0.99Mt was inadequately managed by countries that imported plastic scrap that was previously collected in the United States for recycling (EPA, 2019). In 2010, the U.S. Environmental Protection Agency (EPA) reported that 75.4% of all plastic waste was treated by disposal in landfills, 15.3% was incinerated, and that only 9.3% was recycled (Law et al., 2020).

The most common plastics discarded in the US and considered of high value for recycling are LDPE, high density polyethylene (HDPE), mixed PE/PP, PP, and PET. Plastics deemed to be of relatively low value include PS (polystyrene), PVC (polyvinyl chloride), PC (polycarbonate), PLA (polylactic acid)/bio (Clough, 2001; Law et al., 2020).

A major challenge with plastic recycling includes the incompatibility between certain polymers. This means that some polymers will form segregated phases when molded for reprocessing. Chemical compounds known as compatibilizers are used to combined incompatible phases (Ignatyev et al., 2014). Another issue includes the oxidation and degradation of some of the polymers in landfills, all of which change their properties (Clough, 2001; Burillo et al., 2002).

Compared to other methods of plastic reprocessing for recycling, radiation offers many advantages, including lower energy requirements, the avoidance of chemicals and solvents, and the lack of a liquid neutralization waste. As previously discussed, irradiation of polymers can lead to cross-linking between different polymers without additives, or to chain scissions that lead to polymer decomposition. The possibility to partially degrade heavily crosslinked plastics through radiation also facilitates their melting and molding. Radiation also degrades toxic compounds adsorbed by plastics in landfills, which can cause undesirable color changes and odors (Burillo et al., 2002). Maximizing plastic recycling also prevents its incineration, thus avoiding the release of residual ash and of additional carbon emissions (Law et al., 2020).

Numerous examples have been reported of polymer crosslinking, compatibilization and morphology stabilization (overall form of polymer structure such as crystallinity, branching, molecular weight, and crosslinking) for single phase polymers, polymer blends and composites (Clough, 2001; Burillo et al., 2002). For instance, gamma irradiation of recycled PE (RPE) and of virgin PE (VPE) lead to VPE having a higher degree of crosslinking than RPE, when both samples had the same degree of crystallinity (Adem et al., 1998). Blends of LDPE/HDPE (75/25) were irradiated with gamma-doses up to 2000 kGy. Both tensile stress and elastic modules increased as dose increased also as a result of crosslinking (Miguez Suarez et al., 2000).

Radiation crosslinked EP blends with PP have been found suitable for use as **electrical insulators** (Spenadel, 1979). The use of an additional crosslinker monomer, trimethylolpropane trimethacrylate, was required for using EP/PP blends as **fascia in vehicles**. The crosslinked polymer blends had increased mechanical properties as a result of higher degree of crosslinking (Spenadel, 1979). Incompatible LDPE and polyamide-6 (PA-6) were blended after gamma-irradiation of LDPE. Irradiation oxidized LDPE and introduced polar functional groups that made it compatible with PA-6 (Spadaro et al., 1992). Blending both polymers allow for effective recycling into **food packaging materials**.

E-beam irradiation of PP at doses less than 100 kGy was found to cause chain scission. For the blend, the radiation simultaneously induced crosslinks in EPDM and grafting of PP to EPDM, thus stabilizing the morphology of this blend during injection molding (van Gisbergen et al., 1989b). The PP/EPDM blends find uses in **automotive and home appliances, such as airbag covers and housings, interior surfaces and functioning components (bin mats, buttons and knobs, consoles), static seals, gap filler and exterior finishing**.

Sterilization

Radiation sterilization of disposable plastic medical items (syringes, tubing, vials, gauze, etc.) is a growing segment of the modern industry in many industrialized countries (Kalia and Joseph, 2020). The sterilization by means of irradiation eliminates toxic residues found in chemical sterilization. Major challenges relate to the control of undesired property changes. These changes include post-irradiation degradation in mechanical properties, formation of color centers in transparent materials or discoloration in colored ones. Color arises from a combination of trapped radicals and permanent structural changes in the macromolecules which include conjugated chromophores. On the other hand, discoloration by bleaching occurs by reaction of diffusing oxygen with formed radicals. An in-depth discussion, including several examples of sterilization of materials by irradiation, have been described in review articles (Clough, 2001). This topic is well covered in Chapter 2 of this section (Kalia, 2021).

One example is the radiation sterilization of ultra-high molecular weight polyethylene (UHMWPE) materials used for hip joint replacement, for which long-term stability remains an issue. It has been reported that irradiation in air reduces the molecular weight due to chain scission and degradation. The extent of the oxidation has been found to be dependent on the irradiation time and on the absorbed dose. The oxidation was prevented by irradiating the UHMWPE under a nitrogen atmosphere, followed by its storage in an inert atmosphere. In this way, crosslinking of the PE chains prevailed, and the expected ductile material properties of this polymer were maintained (Streicher, 1995).

Another example is the irradiation of film packaging for food and pharmaceuticals. Preventing the formation of fragmented radiolysis products is a major concern, as these can migrate into the packaging contents. For instance, irradiation of a Nylon/Polyvinylidene dichloride (PVDC)/ethylene vinyl acetate (EVA) barrier film caused changes in mass transfers of the packaging material, with the development of off-odors and taints, even at 1 kGy dose. The results were dependent on irradiation source, gamma or beta (Deschènes et al., 1995).

Other packaging materials have also been investigated using gamma-irradiation. These include PS, polybutadiene and some copolymers, and wood pulp paper, both in the presence and in the absence of antioxidants and stabilizers. In the absence of additives, the effect of irradiation of PS is negligible even at high doses. Antioxidants and stabilizers have been found crucial in polybutadiene and butadiene-containing copolymers. Irradiated wood pulp paper sheets lose some of the bound water (Pentimalli et al., 2000).

Metals, ceramics and nanocomposites (high temperature materials)

High temperature materials are a class of materials having high melting points and that operate at temperatures above 540 °C. It includes some stainless steels, superalloys (alloys of iron, cobalt, or nickel), intermetallics (stoichiometric alloys with well-defined and homogenous composition), refractory metals containing nickel, molybdenum, chromium, and silicon, and certain ceramics (i.e., diamond, graphite, carbides, nitrides, and metal oxides).

Scattering of ions and neutrons by nuclei and electrons in solids can displace atoms from their lattice sites and leave metastable vacancies. These vacancies have distorted chemical bonds that rearrange by atom diffusion excited by other incident electrons (Kiritani, 1986). At higher energies, electronic slowing-down of incident particles prevails, and energy crossover between nuclear and electronic slowing-down depends on ion and particle mass. For Ar^+ ions this is 100 keV, and for Xe^+ , this crossover is 1 MeV (Krashennnikov and Banhart, 2007).

To cause the displacement of atoms, the energy of the incident particles must exceed the binding energy of the atoms in the target material crystal lattice. The binding energies vary from 20 to 40 eV. At lower energies below 1 MeV, inelastic scattering is dominant, and at this energy, roughly 25,000–50,000 atoms can be displaced for the lowest to the highest binding energies in metals, respectively (Zinkle and Matsukawa, 2004; Azevedo, 2011). When electrons with 100 keV of energy hit a solid surface, only a fraction of energy, typically 20 eV, will be transferred to a target atom due to conservation of linear momentum. This is at the threshold of displacing a carbon atom in a graphene hexagonal lattice (Krashennnikov and Banhart, 2007). Consequently, ionization of atoms and breaking of bonds between atoms prevail for high energy electrons.

The following discussion covers developments on ceramic materials, case-hardened steels, and nanomaterials as these comprise the bulk of all commercial products manufactured by different irradiation methods.

Nanocomposites

Design of nanopatterns smaller than 50 nm and manipulation of atoms on ceramics and ceramic nanocomposites require the use of high-energy radiation, such as focused electron beams, high-energy ions, and neutrons.

Among the different radiation-based techniques, electron beam (e-beam) lithography (EBL) and plasma ion implantation (PII) have become two of the most widely used for their simplicity and scalability.

EBL is a technique in which an e-beam is focused by means of external electrical or magnetic fields and used to scan a surface coated with an electron-sensitive film known as resist. It is a nanomanufacturing method used to draw fine lines on semiconductor surfaces, to create micro and nanodevices (Tennant and Bleier, 2011; Groves, 2014; Prakash and Yeom, 2014). This technique replaces photons (photolithography) for creating very small patterns and structures on the resist surface (photoresist).

An EBL instrument is schematically drawn in Fig. 2A. The advantages of EBL include the elimination of photomasks that are required when using photons (wavelengths greater than 50 nm). The resolution limit is not limited by diffraction because the wavelength of high energy electrons is very small. The resolution is affected instead by the spot size of the focused beam and by the backscattering of electrons by the substrate and the resist. Hence, EBL allows the drawing of patterns with resolution smaller than 10 nm (Tennant and Bleier, 2011; Groves, 2014). Aberration is corrected by focusing the e-beam with magnetic instead of electric field, further improving the resolution to about 4 nm (Martinez-Chapa et al., 2016; Manfrinato et al., 2017; Nayfeh, 2018).

The nanofabrication process can be combined with other chemical and physical deposition techniques to create heterostructures, as depicted in Fig. 2B for a magnetic tunnel junction (MTJ) (Singh et al., 2019). In this, the fabrication of $\text{Ni}_{80}\text{Fe}_{20}/\text{Co}_{75}\text{Fe}_{25}/\text{Al-O}/\text{Co}_{75}\text{Fe}_{25}/\text{Ta}$ MTJ begins by etching part of the MTJ structure using e-beam lithography and Ar ion milling (Panel A). The exposed substrate was covered with a thick $\text{Al}_2\text{O}_3/\text{Cu}$ film (Panel B) and liftoff in organic solvent. A Pt thin film of thickness 10 nm was deposited by chemical vapor deposition (CVD) on both sides of $\text{Al}_2\text{O}_3/\text{Cu}$ films. Finally, the junction area was defined by Ar ion milling, in which the Pt films were used as etching masks with $100\text{ }\mu\text{m} \times 10\text{ nm}$ (Panel C) (Niizeki et al., 2003).

Examples of resolutions of less than 4 nm in EBL have been reported for aberration-corrected high-resolution imaging in scanning transmission electron microscopy (STEM) instruments, as presented in Fig. 2C for patterning of ZnO substrates with nano-grid patterns. The resist typically consists of PMMA film. One of the advantages of PMMA, is that this polymer reduces the backscattered electrons as compared to hydrogen silsesquioxane, thus contributing to the enhanced resolution (Nayfeh, 2018). Because of the high electrical conductivity, transparency and precise patterning of these ZnO thin films by means of irradiation, these materials are important components of modern photovoltaic cells, thin film transistors, light-emitting diodes (LED), UV sensors, biosensors, gas sensors, and photodetectors (Kumar et al., 2015).

Boron nitride (BN) is an electrical insulator which is isoelectronic to carbon (diamond and graphene-based materials). As in carbon materials, tetragonal and hexagonal BN materials exist, where the hexagonal structure is the most common and stable at ambient conditions (Eichler and Lesniak, 2008).

Of recent interest to the aerospace industry is boron nitride nanotubes (BNNTs), which can be imaged as being formed by rolling a 2D hexagonal sheet of this material, in an analogous way as SWNTs (Golberg et al., 2007, 2010). The ability of B, particularly its isotope ^{10}B , to absorb neutrons, combined with the lightweight BNNTs that have extremely high tensile and compressive strengths, make this material desirable for future human space exploration (Estevez et al., 2014). Thus, knowledge of the radiation stability of BNNTs is crucial for its successful implementation as structural and as radiation shielding material for space flight technology (Jakubinek et al., 2019).

BNNTs have been irradiated with high-energy electrons and the selective elimination of B and N at specific locations has led to the formation of octahedral fullerene structures (Golberg et al., 1998), changes in nanotube diameter and chirality, and even to curled nanotubes (Zobelli et al., 2006).

Ceramics and metals

Yttria stabilized zirconia (YSZ) is an important ion-conducting material and largely used as thermal coatings (Chen, 2006), dental implants (Camposilvan et al., 2018), catalyst supports in automotive catalytic converters (Dow et al., 1996), as well as in high temperature fuel cells for energy conversion (Resini et al., 2008). The doping of zirconia (ZrO_2) with Yttria (Y_2O_3) yields Yttria stabilized Zirconia (YSZ) ceramics. The doping with a trivalent Y^{3+} cation of a ceramic of a tetravalent Zr^{2+} cation leads to anion vacancies in the crystal lattice for charge neutrality. The existence of these O^{2-} vacancies facilitates the diffusion of oxygen anions across the YSZ crystal, which is instrumental for fuel cell operation and for many catalytic reactions to take place. Thermal diffusion of O^{2-} further increases with decreasing grain size down to the nanoscale, making control over doping and crystal size simultaneously relevant for making materials with enhanced properties (Zakaria et al., 2020).

In YSZ irradiated with Kr^+ 400 keV, the concentration of defects was inversely proportional to the grain size of nanoceramics. The short migration distances in nanograined YSZ allowed radiation induced interstitials to reach the grain boundaries on the irradiation time scale, leaving behind only vacancy clusters distributed within the grain. Radiation-induced grain growth was observed as a consequence of the non-uniform ion implantation. The latter caused cracking of the nanosized samples induced by local stresses at the irradiated and non-irradiated grain interfaces (Dey et al., 2015). This knowledge could motivate the development of YSZ ceramics with engineered defects and at temperatures far below those required for thermal diffusion of doping species.

Ion-implantation is a technique for injecting energetic ions into the surface of a solid target to modify or change the near-surface chemical composition of a material. Sputtering, on the other hand, is the ejection of surface atoms and microscopic particles from a material upon bombardment with high energy particles from a plasma or gas. In ion implantation some sputtering occurs. Hence, ion implantation is also used for changing the defect state of or introducing defects to the target material. Ion implantation offers a clean surface treatment because of the little or no contamination of the target sample. Additionally, heat treatment of the sample is not required to induce transformation (Page, 1991). When plasma is used to generate ions, the process is known as PII. As shown schematically in Fig. 3A, an immersion variant of PII indicates that more than one surface of a material can be coated by this process (Gan and Berndt, 2015).

For thin films, ion beam assisted deposition (IBAD) is widely used, and instead of plasma, another physical vapor deposition technique is employed (Cui and Luo, 1999; Martín-Palma and Lakhtakia, 2013). The ions are accelerated between 20 and 200 keV toward the target sample surface. The ion penetration is limited to few nanometers, and a subsequent thermal diffusion step can be implemented for deposition of ions below surface levels (Gan and Berndt, 2015).

The ion energy and the microstructure of films produced by ion implantation are schematically shown in Fig. 3B. Low-energy ions of ~ 0.1 eV form implanted columnar structures and incomplete surface coverage that result in tensile stress. At intermediate energies of 10–100 eV, a dense film structure with stress that is compressive in nature is obtained. A keV energies, significant atomic rearrangement and relaxation of local stress and strain occur, and a mixing layer is formed at the film–substrate interface that improves adhesion (Gan and Berndt, 2015).

The hardness and stress level of ion-implanted ceramic surfaces change in near-surface, with significant consequences for the friction and wear behavior of ceramic surfaces (Ensinger, 2006). Similarly, the tensile and hardness properties of metals can be altered by induced stress, lattice defects, and carbon or nitrogen ion diffusion (case hardening), a process used to manufacture machine parts, tools, special screws, camshafts and of parts for the construction industry, such as girders, panels, doors and other products that have already been shaped in their final form and that require reinforcing (Pelletier and Anders, 2005; Ensinger, 2006).

For N-implanted steel by ion-implantation and subsequent thermal diffusion, the N-depth profile from Auger electron spectroscopy is shown in Fig. 3C for different ion implantation energy. The resulting hardness of the steels are then compared in Fig. 3D,

Fig. 3 (A) Schematic of a plasma immersion ion implantation system, and (B) schematics of film microstructure deposited using different ion energy levels. The arrows for the low- and medium-energy processes indicate the direction of strain and the resulting forces on the substrate. (C) Auger depth profiles of nitrogen-implanted and ion-nitrided stainless steel AISI 304 at 400 °C and (D) Vickers hardness of nitrogen-implanted and nitridated stainless steel AISI 304. From (A and B) Gan JA and Berndt CC (2015) 4—Plasma surface modification of metallic biomaterials. In: Wen C (ed.) *Surface Coating and Modification of Metallic Biomaterials*, pp. 103–157. Woodhead Publishing. (C and D) Ensinger W (2006) Chapter 18—Corrosion- and wear-resistant coatings formed by ion beam techniques. showing the impact of ion implantation energy in sub-surface ion diffusion for increased hardness of the **nitridated steel casing** (Ensinger, 2006).

Diamond-like carbon (DLC) and DLC hybrid films have been prepared by arc plasma ion sputtering (Delplancke-Ogletree, 2006). During sputtering, the material from the sputter target is atomized by bombardment with ions or with neutral particles. The atmosphere during sputtering is an important parameter, since atomized material can lose energy by collisions with gas molecules. A negative voltage of typically -300 V or more is applied to the target, attracting positive ions as Ar^+ to the target surface. If the energy of bombarding ions exceeds the binding energy of surface atoms in the target, recoil atoms are created. The surface atoms of the target are atomized and travel to the surface that is to be coated. Almost no restrictions in target materials for coating exist, and these include pure metals, semiconductors and insulators (Adachi and Wasa, 2012).

Plasma sputtering deposition of ion-doped DLC films can be carried out in either non-reactive (inert gas only) or reactive (inert and reactive gas mixtures) discharges with single- or multi-elemental targets. **DLC films are used as protective surfaces for prostatic implants, and implantation of ions such as nitrogen, calcium and phosphorus increase their biocompatibility** (Gan and Berndt, 2015).

DLC coatings are also used to protect atomically smooth superlattices and nanocomposites for **magnetic read/write applications** (Delplancke-Ogletree, 2006). Magnetic materials are implanted using magnetron sputtering, a variant of the sputtering technology. In magnetron sputtering, high energy ions (typically Ar^+) bombard and ionize a cathode target surface generated in a glow discharge plasma. Target atoms are ejected from the surface, and ion implantation occurs. Magnets are placed to generate close field loops. The increase in the magnitude of the magnetic fields can increase the plasma density over the target surface, consequently increasing the implantation rates (Coombs, 2012; Exter, 2015).

Semiconductors

Boron doping of DLC leads to **well structures, isolation regions, channel structures, and source and drain regions of Si complementary metal oxide semiconductors (CMOS) transistors**. These are examples of ion implantation for the semiconductor industry (Koizumi et al., 2018).

Another major commercial use of irradiation is that of neutrons from nuclear reactors for doping silicon (Si) with phosphorus (P) (Janus and Malmros, 1976). Si has 23 known isotopes with atomic masses from 22 to 44 amu and the most abundant isotope (92.2%) is the isotope with mass 28 (^{28}Si). Of interest is the isotope ^{30}Si , that has an abundance of 3.1% (Meija et al., 2016). The transmutation reaction involves the capture of neutron and gamma photon yielding ^{31}Si isotope. The latter has a half-life of 2.6 h and it transmutes into ^{31}P by β^- decay process (Haas and Schnöller, 1976). This decay is typical of neutron rich elements, and a neutron (n) is converted into a proton, an electron, and an electron antineutrino. The transmutation reaction is represented as

Silicon is an intrinsic semiconductor and the doping of Si with the electron rich P yields materials with distinct electrical properties. The electrical properties of P-doped Si change with the increasing levels of doping, which is controlled by the upper limit of the ^{30}Si abundance, and by the fluence of neutrons to which the Si wafers are exposed to (Janus and Malmros, 1976). The doped materials are commercially used in **Li-ion batteries and as semiconductors for uses in portable electronic devices** (Haas and Schnöller, 1976; von Ammon, 1992; Ozanam and Rosso, 2016). Advantages of the transmutation process include the energy and time for doping, and the uniform distribution of dopant in the Si lattice as compared to ion implantation or CVD methods that require a second thermal diffusion step to drive the doping elements from the Si surface into the bulk of the crystal (Haas and Schnöller, 1976; von Ammon, 1992).

Metallurgical, glass, paper and plastic industry

Laminated and sheet manufacturing requires strict quality control. Density is the physical property most impacted by the dimensions of laminated and thin-walled products. Online profilometry methods make use of gamma-radiation attenuation to verify the uniformity of the density profile of products. The most conventional method for density determination is the Archimedes method (ASTM B962-17, 2017). However, the existence of open and accessible pores in materials, issues with determining dry and wet densities of materials and their stability is water, make this method difficult to conduct at large industrial scales and with the required levels of precision and accuracy. Densitometry based on gamma-attenuation overcomes these issues, and it is capable of probing for density variations that result from the existence of inaccessible pores, voids and cracks within materials. Gamma radiation sources are ^{137}Cs and ^{141}Am , and a common scintillator detector is sodium iodide (NaI) (Schlieper, 2000, 2001).

The attenuation is proportional to the density of the material (ρ), and the signal intensity related to the mass attenuation coefficient (μ_m) and time (t) by Beer-Lambert's law:

$$I = I_0 e^{-\mu_m \rho t}$$

where $\mu_m = \mu_{m, \text{abs}} + \mu_{m, \text{scatt}}$ and $\mu_{m, \text{abs}}$ and $\mu_{m, \text{scatt}}$ denote the mass attenuation coefficients that result from the photoelectric, absorption and the Compton scattering effects, respectively. This process has been used by the metallurgical industry, which has used automated devices for radiographic density measurement, as represented in Fig. 4A (Schlieper, 2010).

Fig. 4 (A) Schematic of automated gamma-radiation densitometer in use by the steel industry. (B) Schematic of densitometer adapted for measuring wood density in transmission mode (a) and electronics interface to generate a spectrum from the attenuation in gamma radiation transmission (b). (C) and (D) Gamma radiation counts versus calculated experimental densities for different wood samples at 10s and 50s of data collection time, respectively. From (A) Schlieper G (2010) Measuring PM density by going outside the visible spectrum. *Metal Powder Report* 65(3): 10–14. (B–D) Beigzadeh AM, Rashidian Vaziri MR, Soltani Z and Afarideh H (2019) Design and improvement of a simple and easy-to-use gamma-ray densitometer for application in wood industry. *Measurement* 138: 157–161.

Another example of such detector assembly is that for ^{137}Cs and NaI detector with a laminar wood sample placed halfway between detector and source, see Fig. 4B. In this setting, increasing the collection time from 10s to 50s improved the signal in the detector as summarized in Fig. 4C and D (Beigzadeh et al., 2019). However, the shorter detection times still offer reliable and reproducible results for **determining density of wood** from different sources. These changes are expected based on the different contents of cellulose and lignin polymers forming wood.

For materials having more uniform chemical composition and either an isotropic structure or anisotropic structure with preferred orientation of grains, such as plastics, glasses, ceramics, resin-fiber composites, metals and most steels, the same analysis can be applied. A similar principle is applied to measuring packaged solid and fluid levels in opaque containers, in which the attenuation coefficients of packaging materials and that of the packed substances are previously determined (Falahati et al., 2018). This method has been used by the **food and beverage, oil and gas, and construction materials industries**, to name a few.

Antimicrobial properties of irradiation

Gamma irradiation has been found as capable of killing microorganisms in different media. Gamma irradiation acts by breaking different types of chemical bonds in cellular media of the microorganisms. This bond-breaking process produces free radicals that attack the nucleic acid of the microorganism. Sterilization by gamma irradiation is achieved mainly by the alteration of nucleic acid, directly or indirectly, and that prevents the cellular division and microorganism proliferation (Hasanain et al., 2014). The radiation kills insects with doses as low as 500 Gy, and it kills mold and fungus and arrests the biodegradation processes above 10 kGy (Cortella et al., 2020).

Consequently, sterilization by gamma-irradiation has found many different uses in industry. The topics dedicated to **food preservation** and to **preservation of historic and archeological artifacts** are respectively covered in-depth in Chapter 8 (Pillai and Pillai, 2021) and in Chapter 22 of this section (Varquez and Nagai, 2021).

Gamma-irradiation has also been used for sterilization of pharmaceuticals and cosmetics. This includes products in either solid form or in aqueous solution, and polymers in the form of plastic medical products (Jacobs, 1995; Hasanain et al., 2014). Irradiation is particularly effective with heat sensitive pharmaceuticals, and with those incompatible with the most commonly used antimicrobial compound in industry, namely, ethylene oxide (Gopal, 1978). Several **cosmetics and hygiene products** have been safely irradiated with doses of 5–10 kGy. These include **baby powder, makeup products, solid and liquid soaps**. Starting materials include talc, bentonite, wheat and corn starch, and gelatin (Sivri et al., 2006).

Conclusions

The use of gamma radiation and focused e-beams, high energy ions, and neutrons have found many applications in developing a myriad of new commercial products, including new materials design and industrial processing techniques. These processing techniques include quality control, sterilization of medical equipment, of food, cosmetics and pharmaceutical packaging materials. Irradiation techniques have been employed extensively in the development of new polymers, including effective polymer recycling. They have also enabled the development of porous membranes with nanosized pores and of nanocomposites with fiberglass and carbon fibers. The use of radiation has paved the way for the precise manipulation of matter from the atomic level and up to tens of micrometers. Irradiation methods have been instrumental for the development of silicon semiconductor architectures below 10 nm. The use of radiation has enabled the commercial fabrication of non-siliceous electronic components and devices including MTJs, grid nanopattern waveguides for transparent electronic displays, YSZ catalysts and fuel cell electrodes. It also allows for hardening of steel and changing the mechanical properties of ceramics and polymers.

Introduction

Whereas the main focus of this encyclopedia deals with nuclear power, along with the myriad applications of radiation technology to the subjects covered in this section, the other sources of generating heat and electricity such as oil, coal, natural gas, geothermal, and the renewables (hydropower, solar, and wind) also benefit from harnessed radiation. This article is devoted to providing a glimpse of how this is accomplished.

Oil and the petroleum industry

Oil is a fossil fuel that has been historically used for producing electricity. It was one of the principal means of producing electricity in the middle of the last century. However, the OPEC oil embargo of 1973 sent a shock wave through the industry and caused a significant reconfiguration of the global electricity-generating system. Oil currently plays a relatively minor role in the production of electricity in most countries—producing only about 5% or less in the United States today. However, oil is used in prodigious amounts for the transportation sector. The United States relies on oil for about one-third of its total energy consumption. Hence, oil remains a major energy source for transport and heating applications. Oil and petroleum industries are the main end users and beneficiaries of radiotracer and nucleonic gauge technologies (IAEA, 2002, 2004).

Borehole logging

The oil industry is heavily dependent upon the use of radiation to conduct business. Finding new oil fields is a constant effort, especially as traditional sites are becoming exhausted. The standard way to determine the siting of new oil fields is to drill boreholes

(wells) into the earth at strategic locations and then instrument these wells to make geologic measurements at various levels down the shaft. Borehole logging is a term used in conjunction with analyzing these test wells to determine the potential for economically viable oil deposits.

At least four methods based on radiation techniques have been developed to help determine which geologic strata being probed by the boreholes have the highest probability of being developed for oil production (IAEA, 2008). One is based on gamma ray backscattering, in which energetic gamma rays are emitted by two gamma sources placed into the borehole. One emits high energy gammas and the other emits relatively low energy gammas. The detector system placed near these sources in the bore hole can determine the bulk mass of the surrounding material from the intensity of the scattered high energy gammas (due to the Compton scattering effect). It can also determine the constituency of the bulk (i.e. the specific elements in the matter surrounding the borehole) from the intensity of the scattered low energy gammas (due to the photoelectric effect). The goal is to determine high hydrocarbon-bearing regions, characteristic of oil deposits.

A second method is to employ the prompt gamma ray neutron activation analysis (PGNNA) method. By identifying the carbon to oxygen ratio, a strong inference can be made regarding the presence of oil-bearing regions. The carbon to oxygen ratio varies from zero in the absence of hydrocarbons to a maximum value when the surrounding strata are saturated with hydrocarbons.

A third method is to utilize a neutron source in the borehole by employing the neutron backscattering principle to determine the hydrogen content. The americium-241/beryllium system yields neutrons in the 2–10 MeV range and can work well as an appropriate source. Neutron counters such as boron trifluoride detectors are sensitive only to thermal neutrons (neutrons that are thermalized most readily in a region of high hydrocarbons—due to the ability of the hydrogen atoms to rapidly slow down fast neutrons). Further, they are essentially insensitive to the fast neutrons coming from the source (since boron has a very low neutron capture cross section for fast neutrons). Hence, such detectors can be placed very close to the source without difficulty. Fig. 1 illustrates this method.

Yet another use of fast neutrons (though perhaps more expensive) is to utilize a pulsed neutron source by employing a high voltage ion accelerator. By accelerating deuterium onto a tritium target, 14 MeV neutrons are generated. Since the beam current (deuterium in this case) can be turned on and off in an accelerator, a fast beam of neutrons of only about 10 μ s in duration can be produced. A neutron detection system then measures the time it takes for backscattered neutrons to arrive, thus yielding a good estimate of the density of hydrocarbons in the vicinity of the region.

Radiotracers (radioactive tracers) for interwell connections in oil fields; interwell tracing

When primary oil production decreases in a field because of a reduction in the original pressure, water is usually injected to increase the oil production. Injected water in special wells (injection wells) forces the oil remaining in certain layers to emerge from other

Fig. 1 Borehole logging for determining prime oil (IAEA, 2012).

Fig. 2 Principle of radiotracer method for interwell communications (IAEA, 2012).

wells (production wells) surrounding the injector (Fig. 2). This technique, commonly called secondary recovery, provides extractions up to 50% of the original oil in place.

The main radiotracer technique is the measuring of the “time of travel” between injection and production wells. Tritium, as tritiated water, is ideal tracer for water (IAEA, 2012). Using radioactive (and other) tracers to tag the injected material, the following parameters can be determined:

- The percentage of injection water, or gas, flowing from an injector to a specific producer.
- The volumetric sweep efficiency of the flood.
- Reservoir preferential flow trends.
- Fault block or channel communication.
- Whether high-permeability channels are present.

Fig. 3 shows two typical experimental curves in production wells representing “strong channelling” and “normal dispersion” models of underground water transport.

A practical value of tracer tests could be also:

- shutoff of highly watered zones;
- better planning of injection and production wells configuration.

The enhancement of the oil production from the investigation of the secondary recovery processes by radiotracers is estimated to 10–15% of the residual oil for each oil field, which translates into an economic benefit of several million of US\$ per year (IAEA, 2012).

Nucleonic gauges for multiphase flow rate measurement

An increased number of applications with nucleonic gauges in the area of multi-phase flowrate measurement have been reported, mostly by international companies investing in oil production. Here the oil, water and gas flowrates are measured continuously without separating the various phases. Oil-water-gas flow meter nucleonic gauges replace expensive test separators, saving several million of US\$ in one oil field alone (IAEA, 2008).

Multi-Energy Gamma Ray Absorption (MEGRA) gauges for multi-phase flow measurements have been conceived to correct changing fluid parameters that might influence the calibration (e.g. salinity) (Fig. 4). The trend is to replace the radioactive sources with X-ray tubes for higher X-ray flux (increased accuracy) and safer use (e.g. during transportation and/or maintenance). A multi-phase flowmeter that employs the MEGRA concept does not require field calibration, which is a decisive advantage in subsea or marginal field developments (Sowerby, 2002; IAEA, 2008).

Oil refineries

Efficient refinery operation is also a very important part of the oil industry. Whereas it is difficult to install and maintain diagnostic probes inside the distillation towers (due to the extremely harsh chemical and temperature environment), gamma probes can be rather easily installed on the exterior of the towers, and then be moved up and down the tanks to record the composition of

Fig. 3 Two typical experimental curves in production wells representing “strong channelling” (*up*) and “normal dispersion” models of underground water transport (*down*) (IAEA, 2012).

Fig. 4 Multiphase flow meter (MEGRA) installed in oil platform (IAEA, 2008).

ingredients at various vertical levels. Any malfunctions within the tanks can be readily detected. Many of these distillation columns are very large (measuring some 3 m in diameter and ranging to heights of 30 m). Hence, being able to obtain accurate measurements of the contents is very important to the overall economics of the operation (see Fig. 5) (IAEA, 2002).

Neutron backscatter gauges are also routinely used in the oil refinery industry to monitor the level of liquids in tanks and to determine the interface between different liquids. Because hydrogen is a highly efficient neutron moderator, the detection of backscattered thermalized neutrons can be used as an effective measure of the concentration of water or hydrocarbons in tanks.

Fig. 5 Use of radiation gauges to check oil refinery operations (IAEA, 2002).

Petrochemical complexes

The petrochemical plants lie immediately downstream of the oil refinery and in many developing countries construction of the two types of facilities proceeds in parallel. Refineries and petrochemicals plants are generally continuously operating and technically complex. Thus, high economic benefits may be realized by the applications of radiotracer techniques on petrochemicals units. Though radiotracers are useful in solving a wide range of problems, the economic benefits become more pronounced the further “upstream” they are applied. This means that diagnosis of the cracking furnace, primary fractionator and gas separation chain, is of the highest potential value.

Fig. 6 shows a typical Fluid Catalytic Cracking Unit (FCCU) where radioactive tracers are employed to troubleshoot and diagnose the process. The fluid catalytic cracking (FCC) is one of the most important conversion processes used in petroleum refineries to convert the heavy portion of crude oil feedstock into lighter petroleum products, including liquefied petroleum gas and gasoline.

Coal

Fossil fuels provide the largest single source of energy for producing electricity, and coal is still the mainstay around the world. The principal attribute of coal is its availability and relatively low cost. Huge deposits still remain in many regions of the world.

Fig. 6 Radiotracers for diagnosing FCCU (IAEA, 2002).

However, the best low-sulfur coal is being rapidly depleted—requiring more expensive procedures to mine the deeper and scarcer rich supplies. Also, transportation can become a major obstacle. China, for example, is thought to contain the largest deposits of coal of any nation, and these deposits are needed to serve the energy needs of its burgeoning population. Indeed, China is adding large numbers of coal plants for the production of electricity. However, the coal seams are mostly in the northwest region of the nation, far removed from the populous southeast region. The Chinese simply do not have the rail infrastructure capable of moving this source in adequate quantities to the areas requiring power.

But coal has several disadvantages. One is environmental pollution, with both sulfur and nitrogen oxide discharges (leading to acid rain) and carbon dioxide (leading to global climate change). Another is public safety. Far more deaths occur each year from the use of coal (mining and railroad accidents, plus human lung diseases caused by atmospheric smog) than any other fuel source. Furthermore, it is a non-renewable source—available for several more decades, but certainly not for the long term. Finally, coal is the chemical feedstock for numerous commercial products, ranging from laundry detergents to nylon hosiery. It is the key ingredient in the manufacture of iron and steel.

Borehole logging for searching for coal

Fig. 7 illustrates the borehole logging principle for searching coal and minerals, as well as showing a low activity borehole logger system for coal and mineral alignment (Sowerby, 2002).

Analyzing the quality of the coal

The coal industry, which currently accounts for well over half of the world's supply of electricity, benefits directly from using radiation gauges to measure the moisture content in coal, determine the ash content, determine the content of other ingredients (such as sulfur), determine the BTU (heat content), and measure the rate of flow of coal into the furnace (Cutmore et al., 1993; Sowerby, 2002). In order to obtain optimal burn efficiency, coal fired boilers must be fed with coal having a constant caloric value.

One way to obtain the above measurements is to bombard the coal entering the plant on a conveyer belt with cesium-137 and americium-241 (Fig. 8). The Cs-137 emits energetic gamma rays (662 keV), whereas the gamma rays emitted from the Am-241 are a factor of 10 times weaker (~ 60 keV). The high energy Cs-137 gammas are attenuated by Compton scattering (a process essentially independent of the composition of the material). The lower energy gamma rays from the Am-241 are attenuated by the photoelectric effect (which is very sensitive to the atomic number of the flowing materials), thereby easily revealing the presence of iron or silicon in addition to the desired carbon content. Hence, the flow rate of the coal being fed into the furnace is determined primarily by detection of the Cs-137 signal, whereas the percentage of ash in the mixture is determined by a computer analysis of the transmission of both the Cs-137 and Am-241 gamma rays.

More sophisticated radiation gauge systems can also be employed to measure other trace ingredients, including moisture content. One approach is to employ the X-ray fluorescence technique. Another is to employ the prompt gamma ray neutron activation analysis (PGNAA) (Cutmore, 2018). Here the trick is to irradiate the coal along the conveyer belt with neutrons (from a portable neutron generator, such as californium-252 or the Am-241/beryllium system) and cause some of the materials in the coal stream to become activated; thus, releasing prompt gamma rays characteristic of the materials to be identified.

Fig. 7 Borehole logging probe principle (left) and low activity borehole logger system (right) (Sowerby, 2002).

Fig. 8 Analyzing the quality of coal while entering the plant on a conveyor belt (IAEA, 2000).

It is important to determine the sulfur and nitrogen combustion products because these gases are of considerable environmental concern in causing acid rain. Sulfur that resides in the coal entering the plant combines with oxygen and forms a variety of sulfur oxides. Nitrogen is always present because it is the major component of air. Hence, because of the very high temperatures attained in the coal furnace, nitrogen oxides are also formed.

Radiotracer valuation of coal-ash dust cyclone efficiency

In the large boilers for steam production, the coal-ash is carried by air current into the cyclones, which constitute the principal parts of the cleaning system. To diagnose the cyclone efficiency, radiotracer tests have been performed. As an example, a case was studied where the granules of coal-ash were sprayed with an aqueous solution of Tc-99m and then evaporating to dryness. It was proved in laboratory testing that mass labelling had been attained. Thus, the tracer activity was proportional to tracer mass (necessary condition for mass balance). For each test, 30 g of labelled coal-ash was injected with an activity of 200 MBq. The experimental RTD curves for old and new cyclones are presented in Fig. 9. A significant difference was found between the efficiencies of the old and new cyclones for the grain class 0–40%. An improvement in the performance is noted for the new cyclone. For other two classes (40–80 and 80–100 μm), these differences were insignificant.

A new radiation technique, called electron beam (EB) processing, has been demonstrated to effectively remove both sulfur and nitrogen oxides in a single-stage process. By passing the sulfur and nitrogen flue gases under a strong beam of electrons, these pollutants become ionized (hence, electrically charged) and can then be collected on positively charged plates or diverted by a magnet—substantially ridding the flue gas from these environmentally objectionable contaminants. An additional attribute of this process is that these toxic substances can be converted into a commercially viable agricultural fertilizer.

Natural gas

Natural gas has become the recent “darling” for producing electricity in the United States, especially now that fracking technology has been effectively harnessed. The advantages are that these plants can be built quite rapidly and relatively inexpensively, and they can produce reasonably cheap electricity—when the price of natural gas is low. Unfortunately, natural gas supplies (along with the necessary pipeline network) are limited, and volatile gas prices can occur with little notice. The most serious spikes in natural gas prices occur when the demand is exceptionally high (e.g. huge cold snap) and the pipelines cannot handle the load.

Natural gas is a cleaner fuel than coal because it produces no sulfur oxides and about half of the carbon dioxide of a comparable coal plant. However, it does emit nitrogen oxides and, in particular, methane gas. The methane that leaks out in the thousands of miles of gas lines is becoming a sizable contribution to greenhouse gases, since methane is many times more effective than CO_2 in contributing to climate change issues. Perhaps of greater importance, gas is also a non-renewable source of energy. Furthermore, natural gas is a major feedstock to the chemical industry, which creates a mounting concern that an increased reliance on natural gas for electricity production could severely impact the ammonia industry. Enormous quantities of natural gas are required to produce fertilizers used throughout the world.

Fig. 9 Experimental RTD curves in the inlet and outlet of old and new cyclones for class 0–40 μm (IAEA, 2004).

Fluid flow rate calibration in closed conduits using radiotracer methods

Radioactive tracers have become important non-invasive tools for the measurement of flow rates in single phase flows inside closed conduits. Radioactive tracer methods are the most competitive and sometimes the unique method to carry out an online calibration of flow meters installed at any processing equipment without interrupting production, bringing considerable economic savings. The main customers of these methods are petrochemical and chemical plants, natural gas industries, the mineral processing industry, and wastewater treatment installations (IAEA, 2008).

Fig. 10 shows the principle of the radiotracer methods for single phase flow rate measurement in closed conduits for two case studies: on-site flow calibrations on a natural gas line and on a sulfuric acid production line.

Geothermal

Geothermal energy is a term used to characterize the harnessing of heat residing deep within our Earth. Hot magma, resulting from the slow decay of radioactive materials that make up the bulk of our planet (yes, the bulk of the mass beneath the crust of our Earth is heated by radioactive decay!), sometimes protrudes close enough to the outer crust of Earth that it can be accessed. Hence, there are limited places where it is feasible to drill deep enough wells to pipe water down to the magma and tap the steam that is created to subsequently spin electrical generators or heat homes. The principal problem with this source is that there are very few areas where this is practical. Still, geothermal energy may become a significant, long-term contribution to the generation of electricity.

A radiotracer study was carried out at the Rotokawa Geothermal Field, New Zealand (Addison et al., 2017). An injection of 200 GBq of Iodine-125 at specific locations was used to better understand the geology of the field and to optimize water injection and, consequently, to improve the thermal recovery. The Rotokawa geothermal field in New Zealand is one of approximately 15 known high temperature geothermal systems within the Taupo Volcanic Zone (TVZ). In 2010, the total water intake from the reservoir increased from around 15,000 t/day (which supplied the 34 MWe Rotokawa geothermal power plant) to nearly 65,000 t/day with the commissioning of the 138 MWe Nga Awa Purua ("NAP") geothermal power plant. Such radiotracer tests have been employed in this geothermal field many times. Fig. 11 shows the Rotokawa field layout as of the start of the 2015 reservoir tracer test.

Results from these tracer tests have assisted with improving the conceptual model understanding of the field. In particular the lack of any observed connection to the Western Compartment within 1 year of tracer results was consistent with expected

Fig. 10 On-site flow calibration on a natural gas line and on sulfuric acid production line (IAEA, 2008).

Fig. 11 Rotokawa field layout where a radiotracer was injected into injection wells (Addison et al., 2017).

permeability barriers within that part of the reservoir. In addition, the tracer tests assisted in explaining the generally low-pressure drawdown observed in that part compared to other parts of the Rotokawa reservoir.

Increased conceptual understanding from reservoir tracer tests have assisted in providing updates to the numerical model for the field that result in better matches of pressure in both the production and injection areas.

Hydropower

Many countries use water resources for electric power generation. The advantages of hydropower include its intrinsic renewal capability, long-term viability, minimal atmospheric pollution, and relatively low cost. However, dam silting-up problems create difficulties in providing a constant electric power supply, and shortfalls in electricity generation are sometimes experienced during peak demand periods. The increasing demand for electricity calls for expanded exploitation of the hydroelectric dams, which requires heavy dam maintenance. Dams and reservoirs are vital in terms of water supply, irrigation, flood protection, and electricity generation. Large investments are needed for maintaining the efficiency of dam and reservoir operations. Sustainable exploitation of dams requires an in-depth understanding of the silting-up process and monitoring of sedimentation rates using both nuclear and conventional techniques.

The nucleonic density gauge can measure continuously the suspended sediment concentrations providing data for optimal operation and better management of dams and reservoirs (IAEA, 2014). Monitoring the vertical profile of the sediment concentration in water bodies is necessary for dam reservoir flushing. Fig. 12 shows the Seditracker nucleonic gauge for monitoring the sediment density versus time employed in Kinguele dam, Gabon.

This nucleonic gauge can measure relatively large intervals of sediment density in water bodies (0.5–500 g/L). An ^{241}Am radioisotope source has been applied in some cases. In other cases, X-ray generators have been replacing radioisotope sources because of relatively simpler regulation aspects.

Solar

There are basically two types of solar plants in existence today: solar furnaces and photovoltaic (PV) devices.

Solar furnaces work on the principle of utilizing a large array of mirrors to focus direct solar rays onto a “point,” where water is then boiled to make the steam necessary to drive electrical generators. Photovoltaic devices utilize an ingenious application of photocells to convert sunlight directly into electrical current. Neither solar furnaces nor photovoltaic cells can operate without constant access to the sun.

There are applications where solar power can provide an ideal choice for heat and electricity. But the fundamental problem with all forms of solar energy is that it is a very diffuse energy source and it is completely unavailable during the night. Hence, enormous collection areas are needed to capture the quantities of energy needed for modern civilization, especially given the low efficiency of converting sunlight to electricity.

One of the main contributions of radiation technology to solar furnace electricity is in the manufacturing of the vast amounts of materials needed for the collection surfaces required. Radiation gauges are used extensively in making the rolled metal sheets that provide the base metal needed in forming the dishes required to collect the sun’s rays.

Fig. 12 Seditracker nucleonic gauge for monitoring the sediment density versus time in Kinguele dam, Gabon (IAEA, 2014).

For photovoltaic (PV) applications, the main ingredient required for making the system work is the semiconductor. Much the key technology required to manufacture these semiconductors is derived from nuclear technology, where ions are accelerated and implanted into the silicon matrix in a process called doping.

Wind

The wind, of course, is a direct result of the atmospheric pressure differences caused by the sun heating air masses at a different rate in various geographical locations. Because of the rapid fluctuations of the wind, and the low energy density of this source, a huge number of wind turbines must be fabricated and spaced over very large collection areas (much like solar plants).

To better appreciate the scales involved, for a wind farm to produce an amount of electricity equivalent to a comparably-sized nuclear power plant, the amount of material (aluminum, concrete, etc.) required is over 10 times that of the sister nuclear plant.

A perspective on the renewables

Whereas hydro, solar, and wind are generally considered the renewable sources for producing electricity, in reality there is one additional renewable source; namely nuclear power.

Nuclear power? How can this be? Technological advances in extracting uranium from sea water is getting close to becoming a commercial reality. Even though the amounts of uranium dissolved in sea water are very low (parts per billion), new techniques for extracting this nuclear fuel are becoming available to allow energy planners to foresee this as potentially an infinite supply.

Introduction

Most of the chapters of this section of the encyclopedia focus on the various technical aspects of how nuclear radiation can be harnessed to address items of importance within our modern world. The present article is considerably “lighter” in scope. Here we attempt to capture just a glimpse of some of the way’s radiation can help in our everyday life—perhaps qualifying as our silent servant that we don’t normally recognize as even existing.

Personal care

General health

Our personal health is of precious value to every human being. Here we review some of the ways that harnessed radiation helps us get the most out of daily living. We start with perhaps the most valued part of our everyday surroundings: the air we breathe and the water we drink.

Clean air

Air pollution is still a serious problem in many parts of the world. One of the main sources of air pollution is the burning of fossil fuels for heating, the generation of electricity, and for transportation. Noxious byproducts of the combustion of oil, coal, and natural gas include sulfur and nitrogen oxides, as well as particulates that can lead to acid rain, lung disease, etc. All of these sources of energy conversion (including geothermal plants) use the earth’s atmosphere as their ultimate waste disposal medium. There are also many places in the world where chemical residues remain in the air due to the wide-scale use of pesticides in the agricultural industry. Large quantities of CO₂ and methane are emitted from agricultural activities and from primitive societies that burn dung and wood.

Fortunately, radiation technology is being used to reduce many of these pollutants from our atmosphere. The most obvious contribution is the electricity production from nuclear power plants, in which there is essentially no environmental discharge during normal operation. Some may question the issue of the final disposal of nuclear waste, but this (along with the other aspects that need to be included when evaluating the full life-cycle) are dealt with in-depth in another section of this encyclopedia ([Greneche, 2021](#)).

But fossil fuels still remain as the primary energy source in the world today, and will likely remain so for many more decades. Hence, it is important to reduce their polluting discharges as much as possible. Fortunately, one way that radiation technology is helping to clean the flue gas from fossil fuel plants is a flue gas purification system based on electron-beam irradiation that removes the noxious sulfur and nitrogen oxides and even converts them into useable fertilizer ([Chmielewski et al., 2021](#)).

Clean water

The continuing demand for potable water, combined with the gradual decline of fresh water resources, is becoming one of the most urgent global matters for life on this planet. Hence, finding new sources of fresh, drinkable water is a continuing struggle. Radiation tracer technology is a powerful tool in finding out how aquifers are being recharged, the age of such resources, and the purity of the water. More on this topic is included in ([Kumar and Ansari, 2021](#)).

A huge portion of the fresh water used on this planet is in farming. Much of the water now used for growing crops is wasted—i.e., it is simply not efficiently getting to the plant roots where needed. Fortunately, many farms are now employing radiation technology to optimize the use of both water and fertilizer. Neutron gauges are used to determine the moisture content of the soil, to ensure the level of moisture needed but avoid the overuse of irrigation. Tracer technology is used to ensure that the nutrients are getting to the plants in an optimal fashion, thereby avoiding the overuse of fertilizer. Runoff of unnecessary fertilizer results in both polluting streams and wasting the energy required to manufacture the fertilizer. These subjects are treated in more detail in ([Sivasankar et al., 2020](#)).

Given that over 97% of the water on the planet is seawater, and that many major populations centers are situated along the coastline, there is an obvious incentive to explore desalination (i.e., extract the salt and produce drinkable water) to help meet the increasing global need for additional potable water. The concept is not new. In fact, there have been many relatively small desalination plants in operation around the world. But most of them derive their energy from fossil fuel plants, using processes such as water vaporization (leaving the salt behind) or reverse osmosis (driven by electrical pumps that pressurize water and force it through a semi-permeable membrane against its osmotic pressure). But nuclear reactors are well-poised to provide the heat or electricity needed to enable such production of drinking water from the ocean without polluting our atmosphere, and many nuclear projects have provided successful demonstration (<https://world-nuclear.org/information-library/non-power-nuclear-applications/industry/nuclear-desalination.aspx>).

An additional way of utilizing nuclear processes is the potential for treating polluted water to kill bacteria and other pathogens, thus allowing the water to be sanitized for productive uses. This technology ([Macedonio and Drioli, 2010](#)) is especially appealing as we look for ways to deal with international emergencies where potable water is in very short supply and is needed to allow local populations to survive the crisis.

Treated sewage

Increasing urbanization over the last two centuries has been accompanied by an expansion of sewage collection systems that lack the capability and capacity for proper treatment. Liquid waste loads have become so large that the self-purification capacity of downstreams receiving the treated sewage can often no longer prevent adverse effects on water quality—especially for areas of large populations. These wastes now constitute significant sources of water pollution. The industrial effluents carry chemical contaminations such as heavy metals, organic pollutants, petrochemicals, pesticides and dyes, while the discharge of sewage and sludge gives rise to microbiological and chemical contamination of water bodies. The discharge of such materials into water bodies is responsible for risk of infection, health effects caused by contaminated drinking water, and offensive odors. Therefore, all these industrial and municipal wastewater systems need more adequate treatment.

Radiation processing of wastewater treatment is a non-chemical approach based on irradiating the waste stream with high-energy photons or electrons. The energy from these beams is absorbed in the electron system of the wastewater polluting molecules and results in breakage of interatomic bonds—thus, removing the objectionable biological contaminants from the effluent.

In addition to treating wastewater, research has shown that sewage sludge can be disinfected successfully by exposure to high-energy radiation, and the resulting product can be safely used as fertilizer. The technical basis for how all this works for both wastewater and sludge, including successful global demonstrations, is provided in [Chmielewski et al. \(2021\)](#).

Personal grooming and adornment

One of the major advances in the use of radiation is the development of super-absorbent materials. Radiation-grafting and cross-linking processes ([Fulvio, 2021](#)) have allowed the manufacture of disposable diapers used for a full range of ages (babies to those with aging incontinence issues). Feminine products such as tampons also benefit from this technology. Drug stores and grocery stores now often have a major segment of their offerings devoted to stocking this ever-increasing demand for super-absorbent materials.

An extensive variety of clothing materials is currently available—largely as the result of inexpensive cotton now grown in abundance, worldwide, due to new strains of cotton developed using radiation mutation breeding processes ([Sivasankar et al., 2020](#)). Clothes made from synthetics likely also derive benefit from radiation cross-linking or other materials-improvement processes somewhere in the development phase. In particular, we might select the blue polyester-cotton blended shirt because radiation was used to bind special chemicals to the fabric to assure a “fresh-pressed” look all day.

A very large percentage of our population require either glasses or contact lens for improving their eyesight. Without radiation applications, neither would be economical or safe. The glass used in eyeglasses very likely utilized radiation processes that improve the quality of glass (using neutron probes to measure the precise amount of water required during the manufacturing process of making the glass). People wearing contact lenses are likely unaware that the saline solution, used for washing and storing the lenses while not in use, is sanitized by gamma irradiation to kill any microbes that may irritate our tender eyes.

Similar radiation processing devices (including tracer technology) are used in the manufacturing process of cosmetics ([Fig. 1](#)). The exact ingredients used for the cosmetic industry are likely proprietary, but (like the sausage industry) one could be excused for not wanting to know precisely what went into the product. Fortunately, the cosmetics amply featured on the shelves of most drug stores and other convenience stores are safe and can be safely used due to the irradiation of the products to remove any unfavorable parasites ([Fulvio, 2021](#)).

Precious gems

Precious gems are universally admired and desired. But few people know that radiation plays a very significant role in transforming many of them into even more beautiful and desirable acquisitions.

Basically, gems derive their beautiful hues from mineralogical impurities. Jade, for example, derives its deep green because it contains chromium. This element absorbs red, blue, and violet light waves—but not green. Beryl, which is colorless in its pure mineral form, becomes emerald with chromium impurities. On the other hand, manganese impurities in beryl turn it into a pink color.

Gemstones can be enhanced from their natural condition by several means. The principal modes of enhancement are heating, oiling, diffusion, and irradiation. Heating is a widely accepted enhancement process used on rubies, sapphires, topazes, tourmalines, and zircons. Techniques range from simply throwing gems into a fire to employing sophisticated electric or gas furnaces at specific pressures and atmospheric conditions. Oiling is an ancient process that allows oil to seep into the fissures that reach the surface of the stone. This is not a permanent process, but it is often repeated—especially during cleaning or mounting. Diffusion is a method wherein a material such as an oxide form of titanium is coated onto a stone and left there until sufficient diffusion takes place near the surface to change the color. Colorless sapphire is transformed into blue sapphire by this method.

Irradiation is also now in common use to enrich the attractiveness of many precious gems. The following is representative of how radiation is used to enhance the value of several gems ([Matlins and Bonanno, 1989](#)).

diamonds _____ changes the color from an off-white to a fancy color (e.g., green or yellow).
kunzite _____ darkens the color.

Fig. 1 The large array of safe cosmetics now available (Waltar, 2004).

pearls _____ produces blue and shades of gray ("black" pearls).

topaz _____ changes from colorless or nearly colorless to blue; intensifies yellow and orange shades and creates green.

tourmaline _____ intensifies pink, red, and purple shades.

yellow beryl _____ creates yellow color.

In some cases, the irradiation effects will fade away. This is the case when trying to achieve blue, orange, or yellow colors by irradiating sapphire or by irradiating beryl to attain a deep blue color. However, for the cases listed above, the noted properties become permanent.

Perhaps the most successful application of radiation to the gem industry is in the creation of blue topaz. Tens of millions of carats of topaz are irradiated annually. Electron beam irradiation is used for converting white topaz to "Sky Blue" and converting "London Blue" to "Swiss Blue" type colors.

Cobalt-60 is often the radioisotope used to create "Cobalt Blue" topaz. The gamma rays cause electrons to be released from their normal locations in the gem. The resulting color then depends upon where the electrons relocate, as well as the charge of the atoms in their vicinity. These factors control the way the stone absorbs light—thus dictating the resulting color.

Topaz is normally colorless in its pure mineral form. It is only the rare case that blue topaz can be found in nature. When cobalt-60 irradiation was first attempted to convert the much-more-abundant colorless topaz to a rich blue color, the stone changed to a cinnamon brown—and then often faded when exposed to sunlight. However, the irradiation process has since been improved significantly, and the only way to distinguish blue topaz produced by irradiation from the rare natural blue topaz is to go through an elaborate analytical process to measure the light emitted by the gemstone when it is heated. There is no way to distinguish this with the naked eye. Hence, almost all blue topaz stones now on the commercial market are produced by irradiation.

Given the uncertainties in gem processing, there are no guarantees of success for gemstone enhancers. As noted earlier, trace minerals contained in the stones naturally affect gemstone colors, so the combination of trace minerals and irradiation can produce some unexpected results. Hence, many gemstones must be irradiated in order to obtain a few stones that are altered to the desired color (Fig. 2).

Irradiation is also used to change quartz, which is clear and colorless in its pure mineral form of silicon dioxide, into the more attractive and valuable smoky quartz. However, this transformation can be attained only when the colorless quartz contains traces of aluminum. Also, ultimate success depends upon where the electrons settle after irradiation.

The irradiation of diamonds is particularly interesting. New colors are attained in diamonds as a result of the changed crystalline structure. Given the universal attention accorded to diamonds, it is not surprising that diamond was one of the first gems to be tested with radiation. Indeed, the early tests were performed by Sir William Crookes in 1904 (the year after Marie Curie won her first Nobel Prize), when he used radium to produce gamma rays. He was able to achieve a permanent green color. However,

Fig. 2 Precious gems created by irradiation processing. Compliments of Wilson A.P. Calvo, Institute of Energy and Nuclear Research, Brazil.

substantially more success has been achieved in recent times with atomic particles accelerated in a cyclotron. Highly energetic protons, neutrons, or even alpha particles have been used to more efficiently obtain permanent color changes.

The stones that are irradiated today are often then heated to about 800 °C to free them of any residual traces of radiation. Indeed, the irradiation of stones can, under some circumstances such as neutron irradiation, leave the gems slightly radioactive. This has resulted in a potential health hazard in some past situations. Consequently, laws have been passed that require precious-gem enhancers to allow their products to decay to a very safe level of radioactivity before they can be marketed. Some instances have occurred in the past where less-than-scrupulous dealers have placed the enhanced stones on the market before allowing them to decay sufficiently, and there have been a few cases where this has resulted in skin burns. Hence, it is prudent to purchase gemstones from reputable dealers. There should be no concern if the stone is purchased in highly developed countries, but the buyer should beware of such purchases in countries where radioactive testing is not required.

Medicine

A key to the longevity of our lives is modern medicine. Many of the medical products we now take for granted—either over-the-counter or via prescription—are only possible because of harnessed radiation.

Medications

If we take just a few minutes to survey our medicine cabinet, we can now marvel at the incredible number of medications currently available. Most would not be on those shelves without the radioisotope tracers employed in so many parts of the development, testing, and FDA approval process (Venkatesh and Korde, 2021). Carefully selected radioisotopes are routinely used to trace the medical products through the body to be sure the product goes to the proper organs for treatment and that they accomplish the mission intended.

Even the food supplements, conveniently packaged for our use, likely benefited from nutrient tracing techniques afforded by the use of radioisotopes. It is estimated that nearly 80% of the prescriptions and over-the-counter medications and food supplements that we now take for granted would not be available without the testing conducted by the FDA that rely on radiation tracer technology—to be assured that the products accomplish their advertised goals in a safe and effective manner (Fig. 3).

Fig. 3 A typical array of pharmaceuticals at the local drug store (Waltar, 2004).

Sterilization

Customer demand for safe, sterilized products such as bandages, gauze, tissue grafts, burn dressings, surgical dressings, heart valves, plastic and rubber gloves, surgical instruments, etc. continues to increase—especially given the COVID-19 pandemic. The established methods of sterilization include (1) high temperature/pressure sterilization (by dry heat or moist heat); (2) chemical sterilization (e.g., ethylene oxide gas); (3) filtration; and (4) radiation sterilization (Gamma/Electron beam).

In selecting the most appropriate sterilization process, careful consideration needs to be given to ensure that product quality is maintained. The method of choice should not affect polymers, seal strength, label and box adhesion, corrugated and paperboard strength of the container, and also the product's color. Radiation sterilization, being a cold process, helps address these issues more effectively compared to other sterilization methods. Furthermore, this facilitates sterilization of pre-packed, ready-to-use products without any quarantine restrictions. Accordingly, radiation sterilization is becoming the preferred technology for commercial use. See (Kalia and Joseph, 2021) for details.

Routine X-ray applications

Most of us are familiar with the ubiquitous use of X-rays to determine the location of broken bones, tooth cavity detection, etc. This technology is simply taken for granted and the refinements now incorporated in modern X-ray machines are consistently able to provide the diagnostics necessary for an exceptionally small radiation dose.

Attention to serious diseases

Many of us are becoming aware of more advanced applications of nuclear technology for both the diagnosis and treatment of serious diseases. The bulk of this radiation technology to date has been focused on diagnosis, rather than therapy, although applications to the curing of serious diseases is making great progress. See (Venkatesh and Kang, 2021; Kang and Venkatesh, 2021; Shrivastava and Venkatesh, 2021) for substantially more in-depth coverage.

Diagnosis techniques

It is now possible to utilize radiation devices to provide excellent diagnostics of diseases such as cancer, heart, liver, and other serious ailments using tools such as SPECT, PET, and MRI scans. The fundamentals of each are as follows:

- **SPECT** (single photon emission computed tomography): This technique is based on injecting the patient with a radioactive substance, such as Technetium-99^m, and then detecting the traverse of this substance through the body to discover the “hot” spots (i.e., identify the location of the malignancies, where the rate of oxygen intake activity is especially high). SPECT is widely used for routine clinical work because it is relatively inexpensive and utilizes radioisotopes available from nuclear reactors.
- **PET** (positron emission tomography): This technique is based on injecting a different type of a radioactive substance, a positron emitter, into the body and utilizing coincidence counters surrounding the body to isolate the malignancy. PET systems tend to be more expensive than SPECT systems, partly because of the sophistication of the counting system and partly because the radioisotopes that emit positrons typically have a very short half-life (minutes or hours). This latter constraint means that the

equipment for creating the required radioisotopes must be located geographically close to the site of application. However, this technique is being increasingly used because of the preciseness of its diagnostic capability.

- **MRI** (magnetic resonance imaging): This technique is based on applying a strong magnetic field to flip the spin of a hydrogen atom within the imaged organ and utilize the resulting signal for diagnosis. This process does not involve ionizing radiation, but it does depend upon nuclear technology. It is particularly helpful in identifying the density of bone marrow and tissue, thereby obtaining excellent cross-sectional images of the body and its associated organs.

Therapeutic techniques

Much progress has been made over the past few decades to use radiotechnology for either curing serious diseases or at least providing comfort over much longer times than would otherwise be possible.

Most of us are aware of radiation treatments for several modes of cancer. Very high levels of radiation, normally X-ray or gamma ray, are focused on the malignancy to kill the cancerous cells. This can be done via external irradiation (teletherapy), i.e., placing the patient in a prone position and moving the radiation beam around the patient (taking care to focus the beam on the target area and minimize damage to surrounding healthy cells) or placing radioisotopes inside the body (brachytherapy) to get the radiation as near as possible to the malignancy. Brachytherapy normally consists of X-ray, gamma ray, or beta ray radioisotopes. However, an evolving new approach is to utilize alpha emitters, since alpha particles pack a substantially higher potency at close range. This appears particularly promising for diseases such as leukemia, where the malignant cells are not confined to a particular area of the body.

A rather astounding fact is that one out of every three patients entering a U.S. hospital or medical clinic derives direct benefits from nuclear radiation medical treatments. This is a rather stark reminder of how much we really owe to the medical benefits of harnessed radiation.

Food

One of the most significant advances in our global food supply over the past century is the use of radiation to develop and improve the production of a huge variety of foods that we now take for granted. As detailed in Chapter 6 (Sivasankar et al., 2020), basic foods such as new grains and vegetables have evolved over eons of time on a continuing (but slow) basis as they have adapted to their changing environment.

But, radiation techniques have been developed and put into full production to accelerate this natural mutation process by irradiating seeds or stocks, with resulting varieties that have substantially better yield, better disease resistance, better flavor and color, more efficient use of fertilizer, etc. (Sivasankar et al., 2020). In fact, from an economic perspective, radiation mutation processes have resulted in by far the largest economic impact to scores of nations around the world than from any other application of radiation technology. We are now blessed with an abundance of food varieties that are able to grow effectively in almost any environment. This technology will undoubtedly become even more important as we seek ways for field produce to survive and thrive to meet global climate change conditions.

When going to our local store or supermarket, we seldom worry about the quality of food we purchase. Why? For the most part, all products on the shelves have been sanitized and scrutinized to assure us that the food is safe to eat. Most raw products have gone through various screening processes and many arrive at the store wrapped by sanitized materials that have been irradiated to ensure cleanliness. As noted below, some of the products have been irradiated to ensure long shelf-life (Pillai and Pillai, 2021).

We can fry our eggs to our perfection on a pan equipped with a special coating (developed by a radiation cross-linking process) to inhibit sticking. Radiation gages likely determined the thickness of this coating and assured that it was properly adhered to the metal. The silverware used during our meal undoubtedly benefited from radiation thickness gages during the making of the sheet metal from which the utensil were subsequently stamped. Further, we can be assured that our full packages of breakfast cereal were weighed correctly or precisely measured by radiation leveling or density gages (Thereska and Brisset, 2020) to ensure that the weight and volume stated on the cardboard container were accurate (Fig. 4).

Despite the positive situation above, there remains caution for some foods, such as fish, poultry, and red meat—particularly for open air markets—since some bacteria and pathogens remain hidden and can pose a health risk if not properly cooked. Some estimates indicate one-third to one-half of all food harvested in the field becomes spoiled before reaching the dinner plate. In fact, this spoilage can reach up to 90% for fish. We can look forward to the day when there is sufficient public acceptance of food irradiation to further improve the safety of such products (Pillai and Pillai, 2021).

But even now, several food products benefit from irradiation prior to reaching our kitchen. Most spices are irradiated to kill unwanted pathogens, and numerous other products are undergoing approval by the Food and Drug Association (FDA) in the U.S. As one small example, sealed containers of the creamer that we may pour onto our coffee or tea can remain on our shelf for long periods without refrigeration because the container was irradiated prior to being filled in order to assure the absence of microbes. The shrink-wrap or aluminum foil that radiation processes help to produce provide convenient and safe ways to store unused food for consumption at a later time. Fortunately, food irradiation is slowing becoming more common—especially in many countries outside the U.S.

Fresh fruit and vegetables should constitute a significant portion of our daily diet. Such commodities cannot always be readily at hand during some seasons of the year. But, when available, we can be thankful for the much larger variety and volume of such foods

Fig. 4 Breakfast cereals, with proper fills assured via radiation gages (Waltar, 2004).

made possible by the greatly accelerated agricultural breeding processes now in practice, globally, by using either mutation or tracing processes (Sivasankar et al., 2020).

Much of the food on the grocery shelves is contained in bottles or cans. As noted earlier, a high volume of the glass and metal used in making these bottles and cans are made economically by radiation processes (e.g., improving the quality of glass). Radiation gages are often used to ensure proper thickness of many sheet metals used for manufacturing the cans. Given the numerous numbers of bottles and cans used in modern commerce, the employment of radiation devices to measure the proper filling and sealing processes for rapid automation is essential in keeping production costs to a minimum. We need not worry about whether our can of soda or beer has been filled to the proper level. That has been taken care of by the use of radiation level gages (Fig. 5).

Fig. 5 Bottled beverages—all assured of being filled to the brim via radiation gages (Waltar, 2004).

Personal conveniences

New products

A quick stroll through the modern cities of today bear little resemblance to the cities and towns of the “yesteryears.” Thick wooden plank floors of the “Old West” still have a lot of charm, but many of the floors now appearing in numerous office complexes, shopping malls, airports, and grocery stores have very different look. They are products of radiation cross-linked polymers. Such floors are not only beautiful, they are long-lasting (excellent abrasion resistance) and have low maintenance costs.

Radiation cross-linking is based on the effects of polymers being exposed to high-energy beta and gamma rays. In the process of cross-linking, when the material absorbs radiation energy, chemical bonds are broken and free radicals are formed. These free radicals then react to form new chemical bonds—forming an extremely resistant “network” (Fulvio, 2021).

Radiation cross-linking is basically suitable for all types of plastics that can be chemically cross-linked by using radical initiators such as peroxides. Unlike chemical cross-linking methods, radiation cross-linking takes place at low temperatures. The most voluminous commercial polymers to be radiation cross-linked are polyethylene (PE), polyamide (PA), polybutylene terephthalate (PBT), and polyvinyl chloride (PVC). The old process of chemical vulcanization of rubber for tires has largely been replaced by radiation cross-linking because the latter technique is done at low temperature and with greater precision and without fluctuations in quality.

This radiation technology has also been applied to developing new automotive primers and topcoats, and specialty coating for wood and paper.

Wood remains a highly valued material for making fine furniture, in addition to providing a key structural material for buildings. In order for such wood to provide long-term service without cracking, it is essential to remove the necessary amount of moisture before using. Neutron probes provide perhaps the most accurate way of determining when the wood has dried to the point for commercial use.

When cleaning furniture, floors, or pretty much everything around the house, new detergents and other cleaning solvents have emerged in a very cost-effective basis due the automation of mass production lines made possible by radiation level and density gages that allow the precise processing essential for quality products.

Transportation

The use of personal automobiles has transformed travel over the past century, and there is no indication that such mobility in freedom in travel will fade in the future. Knowing that our car will start instantly and provide reliable transportation for many, many miles is a luxury now taken for granted. But it was the use of radioisotopes to determine engine wear that was largely responsible for the fine-tuned engines now in common use. Plus, as outlined in (Thereska and Brisset, 2020), the materials used in the manufacture of the car were largely the result of radiation gages and measuring devices (i.e., the glass, body shell, etc.) As noted above, tires are now normally vulcanized by radiation cross-linking—rather than the older sulfurization process. Further, the pavements that are now available for smooth driving experiences have benefited by radiation compaction instruments prior to the final surfacing (Bjornstad, 2021).

Of course, any mode of travel involves the element of time. It may come as a surprise to some readers that the most precise clock ever invented and put into commercial use is the atomic clock. This device measures the electromagnetic signal that electrons in atoms emit when they change energy levels. Since 1968, the International System of Units (SI) has defined the second by measuring two energy levels of the ground state of the cesium-133 atom. It is accurate to within 10^{-9} s per day (approximately one part in 10^{14}) (https://en.wikipedia.org/wiki/Atomic_Clock).

Entertainment

Another great convenience in our daily life is to keep up with the news and be able to watch TV or listen to the radio for further entertainment. One of the main reasons that newsprint or magazine print is relatively inexpensive is due to the use of radiation gages in the high-speed automation in the production of the paper itself for the automation processes employed in making paper (Thereska and Brisset, 2020). Both the radio and television sets benefit from the wires made possible by radiation-treated heat-shrink insulation.

But even more common as we go through the day is our unchallenged addiction to computers and cell phones. The basic ingredient in both devices is the microchip, which requires specialty doped semiconductors to provide their power and convenience. The base material for the semiconductors is silicon, one of the most abundant elements on the planet. But raw silicon is neither a perfect insulator nor a perfect conductor. Rather, it is somewhere in between. By imbedding a smattering of elements such as boron, phosphorus, arsenic, gallium, or others into the silicon matrix, the flow of electricity through the silicon can be controlled. This allows the production of transistors, the building block for the production of microchips.

In order to make these specialty semiconductors, particle accelerators are used to propel these charged elements (ions) into the silicon matrix, forming N-type materials (molecules having an excess of free electrons) and P-type materials (molecular structural holes requiring free electrons). These units are then assembled into the transistors and microchips we require for use on a daily basis.

New technologies are being investigated for developing self-charging batteries, using radioactive carbon-14, that may 1 day allow users to keep cell phones charged essentially forever (<https://newatlas.com/energy/nano-diamond-self-charging-batteries-ndb/>).

One of the pleasures of modern life is to enjoy great art. Although we may not be aware of it, precious paintings are always vulnerable to forgery—as well as deterioration due to environmental factors. Hence, radiation has been used on a rather frequent basis to assure us that the paintings advertised as originals are indeed the real thing, and that they can be well preserved (Varquez and Nagai, 2021).

Home and garden

One of the marks of an inviting home is the incorporation of flowers in and around the house. Nothing stimulates our sense of sight and smell like the beauty and fragrance of a bouquet of a dozen roses or a flowering patch of multi-colored rhododendrons. Using the same radiation mutation technology outlined in the food section above, an incredible number of new flowers have been developed globally over the past several decades. The worldwide floriculture (flower) industry is estimated to be worth \$70 billion a year, and it is growing rapidly, especially in the developing nations. The actual value of this global industry will likely never be known very accurately, because much of this work has proprietary value. Developers are not generally willing to reveal their secrets on how, for instance, they have been able to utilize radiation to develop varieties of flowers having creamy strips with colors ranging from yellow to white, purple, yellow orange, and orange.

Any good gardener knows that the proper fertilizer is key to growing both fruits and vegetables, along with hearty flowers. The irradiation of sewage to both disinfect the raw effluent AND provide useable fertilizer in the process bodes well for the Master Gardener wishing to grow productive plants consistent with environmental stewardship.

One of the most common supplies in any home shop is sandpaper. This is another product we simply take for granted without realizing that there are normally three processing steps in the manufacture of sandpaper based on radiation technology: radiation thickness (depth) gages to (1) determine the proper thickness of the underlying paper, (2) determine the appropriate thickness of the glue, and (3) determine the size and thickness of the grit being bonded to the paper (Fig. 6).

Personal safety

Daily hazards

Perhaps the most noticeable application of radioisotopes to modern home and office safety is the common smoke detector. This device contains a small amount of a special radioisotope (often americium-241, although plutonium-239 has been used in numerous smoke alarms in Russia) that constantly emits alpha particles into an ion chamber. During normal atmospheric conditions, a small but steady electric ion current is actively recorded. However, if a fire occurs, smoke particles enter the chamber and reduce the ion current. The change in current triggers the smoke alarm. These compact smoke alarm devices have saved untold lives as well as valuable property throughout the world (Fig. 7).

Crowded theaters represent a hallmark of successful movies, live performances, concerts, and other artistic gatherings. But any time a throng of people becomes wedged into cramped quarters, there is always the potential for fire or other safety threats that provide an impetus for prompt evacuation. In such situations, it is comforting to know that the omnipresent exit sign will always stay illuminated, even in a blackened theater, because it is powered by radiation. By employing the 24-h reliability of the

Fig. 6 Sandpaper—made via three-step radiation manufacturing process (Waltar, 2004).

Fig. 7 The common household smoke detector (Waltar, 2004).

Fig. 8 A typical exit sign powered by radiation (Waltar, 2004).

luminescence property of radiation, these signs powered by radiation can be relied upon to operate under any and all circumstances. The glass tube spelling "exit" is painted with a luminescent material and is filled with tritium gas. The constantly emanating electrons from the tritium impact this special paint and cause the emission of light visible to the human eye. Such signs are now located in most public buildings in the Western world and have undoubtedly saved many lives when buildings need to be evacuated during power failures and other hazardous conditions (Fig. 8).

Airport screening

All of us are acutely aware of the passenger and luggage screenings that now routinely takes place in all modern airports around the world. Although this process is at times annoying, we recognize the need for taking such measures—especially since the terrorist attacks of 9/11. X-ray machines are an all-too-familiar fixture through which we must pass before heading to our departure gate. However, many of these machines are capable of producing only pictures that often cannot distinguish between a block of plastic explosives and a wedge of cheese. They did not prevent the hijackers from boarding airplanes on the morning of September 11, 2001 and carrying out their morbid plans. This placed considerably more reliance on the detection operations than is desirable—and it is why more-advanced detection machines are being designed for implementation.

One fairly recent development is the application of neutron activation devices to detect hidden explosives. A technique now employed in many airports is to direct a beam of neutrons on samples taken from passenger luggage. This transmutes a material such as nitrogen (a common ingredient in explosives) into a radioactive isotope that emits a characteristic radiation that can be

detected. Whereas this provides positive identification of suspicious materials, this procedure is generally not suitable for high-speed throughput of luggage inspections. Rather, such techniques are more applicable for border security operations (Strellis and Gozani, 2020). Hence, most airports currently utilize an ion mobility spectrographic system. In many cases, a beta emitter such as nickel-63 is used to create the ionization required for sample investigations. The most likely procedure used when airport security personnel take a “swipe” around your personal laptop computer or other carry-on luggage is based on X-ray backscattering (<https://www.epa.gov/radtown/radiation-and-airport-security-scanning#about-radiation>). We are comforted to know that a wide variety of radiation processes can be used to ensure our protection from terrorists when we board a commercial aircraft.

Airplane wings and other structures

It is difficult to imagine how 21st-century life could be accommodated without the convenience of air travel. We might put quotes around the word “convenience.” This mode of transportation has become considerably more cumbersome since the terrorist attacks of 9/11. Still, given the hectic pace of modern life, the time required to traverse the states in a train or cross the ocean in a ship for reasons other than pure leisure have become unthinkable. Air travel has transformed modern life, and there is no turning back.

Whereas air crashes still do occur, the reality is that air travel is by far the safest mode of transportation (as measured by life-lost per mile). Such a safety record seems counterintuitive, given the speed of such vehicles and the obvious concerns should some type of major failure occur while at 30,000 ft.

Certainly, there are significant safety factors built into the design of such aircraft, knowing that storms and other acts of nature can bounce these airfoils around. But logic dictates there are practical limits to the thickness of materials that can be used in making the wings and the body, lest the airplane be so heavy it will never leave the ground. Hence, it has long been a substantial comfort to know that the critical welds on those aircraft are routinely inspected by radiography. All commercially licensed aircraft have regularly scheduled inspections in which either neutron or gamma irradiation can be employed to inspect crucial areas such as the welds that attach the wings to the body. Any flaws revealed by this system result in immediate attention for appropriate repair. A popular source of neutrons for accomplishing this task is californium-252, a spontaneous neutron emitter that does not occur in nature but is made in nuclear reactors for such purposes. Neutrons are often needed for military aircraft that employ composite construction techniques, whereas gamma sources work well for the metallic construction normally employed for commercial aircraft.

Other structures in our normal travel patterns that demand careful attention to welds are the steel bridges that we count on for safety on our nation’s highways. There are now over 615,000 bridges in the US, the majority of which rely on steel structures for stability. Here again, radiation technology is periodically employed to ensure the structural reliability of key welds.

Runway lights

Another unique application of radiation is in providing the source of energy for airport runway lights. Given the possibility of a blackout at airports, one of the special safety features is using tritium to invoke the luminescent property of radiation [illustrated in Fig. 9 of (Waltar, 2021)] to assure a 24-h reliable light source—independent of weather or other confounding factors. Krypton-85 is also used for this purpose. Clearly, radiation provides a major contribution to the safety of modern air travel.

Safety from crime

Crime has undoubtedly been a distasteful part of humanity as long as history itself. And with the advancements in technology, crime has become increasingly more sophisticated. Consequently, it is necessary to employ new techniques in order to both thwart criminal activity and provide ways to track down and convict the offenders.

As might be expected, the activation property of radiation is a strong ally to aid in criminal investigations. Being able to trace the paths of guns, knives, and personal effects such as gloves and shoes can be exceptionally helpful in solving difficult criminal cases. Even trace amounts of “tell-tale signs” can be analyzed by using radiation techniques to help bring about justice. By sampling only a small amount of dirt on the shoes of a suspect in an appropriate radiation detector, the precise ingredients of the sample can often be matched to other soil samples to determine where the suspect previously has been.

Neutron activation analysis (NAA) was used as early as the 1950s by criminologists. This process involves placing a sample of evidence found at the crime scene into a nuclear reactor and irradiating it with neutrons (Fedchenko, 2021). The neutrons collide with components of trace elements contained in the sample, causing them to be transmuted into other isotopes that subsequently decay and emit gamma radiation of a characteristic energy level. This allows accurate identification of many constituents in the sample. The amazing thing about this procedure is that it will work for a small sample of hair. As many as a dozen or so different elements can be identified in a single strand of hair.

DNA testing

One modern technique that is being used more frequently to bring criminals to justice is DNA analysis. Exceptionally minute quantities of “residuals” associated with suspected persons can be used to provide positive identification. By matching residuals at the scene of the crime (such as blood stains, saliva, semen, or hair) with the suspect, prosecutors have powerful evidence in their arsenal.

Such analyzes have been used in famous cases and in other circumstances, such as in the O. J. Simpson murder trial, the President Clinton incident with Monica Lewinsky, and the positive identification of the deaths of Saddam Hussein's eldest sons. What may not be known to many people is that radiation often plays a key role in the analysis.

"DNA fingerprinting" has gained considerable popularity and glamor in the recent past because we now know that every person on Earth has his or her own unique variation of the DNA molecule—the only exception being identical twins. This affords forensic experts the possibility of providing a positive linking of crime scene trace DNA residue to only one person in the universe. However, the processes involved in "DNA fingerprinting" are quite complex (Bowling, 1996). Hence, DNA analyzes have sometimes been discarded in courts of law because of the lack of precision in the sample collection or in the measurement techniques. Also, since DNA analyzes are time consuming and expensive to perform, other "fingerprinting" techniques are being developed for more frequent applications.

The techniques used for DNA fingerprinting are based either on the type of genes an individual has or upon the amount of reoccurrence of a certain pattern of nucleotides in his or her genetic material. The former approach to determining a DNA fingerprint is called the polymerase chain reaction (PCR) technique, wherein the gene types of an individual are matched. The latter approach is called the restriction fragment length protocol (RFLP) technique, wherein the repetition of nucleotide patterns within a chromosome is measured to obtain a DNA fingerprint.

The PCR method does not involve radiation techniques in the DNA matching process. Rather, it is based upon duplicating a single strand of DNA in an exponential fashion, such that 20 replication cycles yield about a million copies of the original DNA. These new copies are placed on a sheet of nylon. Gene probes, which bind to certain genes, are then introduced, and they will attach to specific genes on the DNA strand. A special indicator solution, unique to each gene probe, is then added, and when this indicator locates a probe that is attached to a "target gene," a blue dot appears on the nylon strip. This series of blue dots and blank misses is the "DNA fingerprint." The advantage of the PCR method is that it requires only a very small sample size—perhaps the size of the tip of a pin. Furthermore, it takes only about 2 or 3 weeks to complete the procedure. However, the disadvantage of the PCR method is that it is considerably less accurate than the RFLP method discussed below. The probability of error in matching individuals with the PCR sample may be from one in a hundred to one in two thousand. Whereas this might sound quite precise, it may be insufficient to convince a jury "beyond a reasonable doubt." In fact, it was largely due to this possibility of error that the analysis provided by this approach was discarded in the O. J. Simpson trial (Cohen, 1995).

The RFLP method is based on employing an enzyme that can locate a certain string of nucleotides in the DNA molecule. After cutting the DNA into a series of variable lengths, these pieces are put into a special type of gel at one end of a container that has electrical plates affixed to both ends. An electrical current is then passed through the solution in a process known as electrophoresis. The pieces of DNA move through the gel at different rates because of their different sizes. The gel is subsequently removed and bathed in a solution containing four types of radioactive probes, each of which binds to a different nucleotide on the end of the cut-up DNA pieces. A piece of X-ray film is then placed on top of the gel, and a radioactive tag, normally phosphorus-32, is then used to expose the film. The strips of white at different locations on the exposed film indicate how far the different pieces of DNA have moved. This pattern is the classic "DNA fingerprint."

This procedure can take a much longer time to complete than the PCR method, primarily because of the small amount of phosphorus-32 that is tagged to the DNA. It may require up to 2 weeks to significantly expose a piece of X-ray film. In addition, the film must be separately exposed for each of five or more areas being tested, each taking an additional week. Upon completion of the procedure, the film is often scanned into a computer to obtain precise measurements. All of this could take 3 or 4 months. However, the reward is that the accuracy is exceptionally high. It is from five to a thousand times more accurate than the PCR method. In fact, some of the experts at trials have testified that the error in this method, based on radioactive techniques, may be only about one in a hundred million. When a prosecutor tries a case and can show that the chance of the DNA's not being that of the defendant is one in a hundred million, he or she has very compelling evidence.

To sum up the DNA-fingerprinting approach, this area is getting increasing attention as a way to match the DNA found in substances at the scene of a crime with the unique DNA of a suspect. Whereas very precise matching can be done using the approach based on employing radioisotopes, the process is expensive and time consuming. Hence, nonradioactive techniques are becoming popular for routine investigations. But for situations where preciseness really matters, the RFLP method, which relies on radiation techniques for crucial steps, remains an important forensic tool. An error rate of only one part in a hundred million can free an innocent person or send a murderer to jail.

Border security

With the ever increasing inflow of international goods crossing our borders on a daily bases, it is comforting to know that increasingly sophisticated methods are being developed and employed at our borders to thwart the attempts by terrorists and others with criminal intentions to threaten our safety. Two chapters are devoted to this important task in this Section (Patton, 2021; Strellis and Gozani, 2020).

Communications

It was shortly after the shock of 9/11 that the United States became immobilized with the news that anthrax bacteria had been sprinkled on some of the letters entering the domestic mail system. Anthrax-laced letters appeared in the offices of key members of the US

Senate, causing complete evacuation of several federal office buildings for a substantial length of time. As officials scrambled for ways to screen mail to be sure it was free of this deadly “dust,” inquiries were made to ascertain whether electron-beam accelerators could be used to kill the anthrax, thereby cleansing the mail. Quick demonstrations resulted in a positive answer and the use of radiation was quickly adopted as a safe and effective measure for such application.

Whereas there clearly would be logistical difficulties in requiring similar sterilization for the full mail system of any major country, and certainly so for the United States, this system did work for the limited volume of mail needed to keep the wheels of government moving in the United States. Improvements on the system have been subsequently made to refine the process and avoid many of the initial problems, such as causing some of the paper to be slightly discolored (*Nuclear News*, 2003). Many of these systems now remain in standby for similar emergencies.

Summary

It is impossible to go through a day living in our modern world where radiation technology has not provided a significant contribution to our personal care, conveniences, or safety. From the air we breathe, the water we drink, the food we eat, the medicines we take, the clothing we wear, the mobility we take for granted, the entertainment we enjoy, our improved understanding of our cultural heritage, and the personal protection we take for granted, harnessed radiation is there as our unseen but powerful servant.

Glossary

Absorption The natural assimilation or incorporation of fluids into interstices, i.e. liquids in solids. In absorption, the dissolved molecules are incorporated within the structure of the solid (such as soil or a rock mass) and the fluid is held mechanically.

Activity The rate of disintegration (transformation) or decay of radioactive material per unit time.

Adsorption The surface retention of solid, liquid, or gas molecules, atoms, or ions by a solid or liquid advection. A process by which solutes (dissolved constituents) and/or heat are transported by the bulk motion of groundwater flow.

Alpha particle A positively charged particle (helium atom) ejected spontaneously from the nuclei of some radioactive elements.

Aquifer A water-bearing or saturated formation that is capable of serving as a groundwater reservoir supplying enough water to satisfy a particular demand, as in a body of rock that is sufficiently permeable to conduct groundwater and to yield economically significant quantities of water to wells and springs.

Argillaceous formation Sedimentary formation (shale) that has fine grained clay minerals.

Becquerel (Bq) 1 Bq represents a rate of radioactive decay equal to 1 disintegration per second, and 37 billion (3.7×10^{10}) Bq equals 1 curie (Ci).

Beta particle A charged particle (with a mass equal to $1/1837$ that of a proton) that is emitted from the nucleus of a radioactive element during radioactive decay (or disintegration) of an unstable atom. A negatively charged beta particle is identical to an electron, while a positively charged beta particle is called a positron.

Carbon-14 dating A method for dating the age of a particular material using the ratio of carbon-14 (^{14}C) to carbon-12 (^{12}C) based on the half-life of ^{14}C .

Carbonate A sediment formed by the organic or inorganic precipitation of carbonate minerals.

Condensate Water that has been produced by the cooling of steam in a condenser.

Dating of groundwater The assessment of relative concentrations of radioactive environmental isotopes, such as tritium (^3H), chlorofluorocarbons (CFCs), and carbon-14 (^{14}C), have been used to determine the age of groundwater.

Daughter products Isotopes that are formed by the radioactive decay of some other isotope.

Delta (δ) notation Part per thousand (‰; per mil).

Denitrification A redox process by which nitrate (NO_3^-) in anaerobic systems can be converted by bacteria to gaseous nitrogen species such as elemental nitrogen gas (N_2), nitrous oxide (N_2O), or nitric acid (HNO_3).

Deuterium An isotope of hydrogen with one proton and one neutron in the nucleus.

Discharge area The portion of the drainage basin in which the net saturated flow of groundwater is directed toward the water table.

Discharge velocity/discharge rate The speed at which a given volume of water flows through a given unit of the porous medium's total area perpendicular to the direction of flow.

Dissolution The process by which minerals dissolve into water.

Distillation The removal of impurities from a liquid by heating it and condensing the vapor.

Evaporation The conversion of a liquid to the vapor state by the addition of latent heat below the boiling point of the liquid.

Evaporite A sediment produced from seawater or salt lakes in tidal areas under arid conditions as a result of extensive evaporation.

Evapotranspiration The process whereby water is evaporated from plants, soils, and surface water bodies.

Freshwater Surface water or groundwater that is not composed of or influenced by saltwater or salt-bearing rocks.

Geochemical processes The chemical changes and reactions that groundwater undergoes as it moves through the subsurface.

Groundwater The excess soil moisture that saturates subsurface soil or rock and migrates downward under the influence of gravity.

Half-life The time in which one half of the atoms of a particular radioactive substance disintegrate into another nuclear form.

Hydrologic cycle The worldwide process, without a true beginning or end, that graphically or mathematically represents the movement of water from the oceans to the atmosphere, to land, and back to the oceans through the process of evaporation, precipitation, infiltration, transpiration, overland flow, base flow condensation, and runoff.

Hydrology The study (or science) of water including its circulation, distribution, and chemistry.

Hydrosphere The water of the earth (the sphere), segregated from the lithosphere (rocks of the earth), biosphere (biota of the earth), or atmosphere (air of the earth).

Infiltration The process by which water enters the subsurface.

Isotope Two or more forms (or atomic configurations) of a given element that have identical atomic numbers (the same number of protons in their nuclei) and the same or very similar chemical properties but different atomic masses (different numbers of neutrons in their nuclei) and distinct physical properties. ^{12}C , ^{13}C , ^{14}C are isotopes of the element carbon, and the numbers denote the approximate atomic masses.

Isotopic enrichment A process by which the relative abundance of the isotopes of a given element are altered, thus producing a form of the element that has been enriched in one particular isotope and depleted in its other isotopic forms.

Lake A freshwater or saline inland body of water enclosed within a depression of the earth's surface, either natural or man-made.

Lithology The scientific study of rocks.

Magmatic Water The water derived from a magma or exists within magma.

Metamorphic water Water produced during rock metamorphism.

Meteoric water Groundwater that originates in the atmosphere and reaches the zone of saturation by infiltration and percolation.

Meteoric waterline The relationship between deuterium ($\delta^2\text{H}$) and $\delta^{18}\text{O}$ concentrations in water from global precipitation surveys.

Methanogenesis The process of generation of methane by microbes.

Nitrification The inorganic process whereby oxygen is consumed in groundwater through the oxidation of ammonia (NH_4), producing nitrate (NO_3^-).

Noble gas A gaseous chemical element that does not readily enter into chemical combination with other elements. An inert gas. Examples are helium, argon, krypton, xenon, and radon.

Paleoclimate assessment To assess the past climates.

Paleowater Also known as fossil water. The ancient body of water present in an aquifer for millennia.

Parent A radionuclide that upon radioactive decay or disintegration yields a specific nuclide (the daughter).

Permeability/permeable The property or capacity of a porous media (soil, rock, or sediment) for transmitting a fluid.

Porosity A measure of the void (i.e., "empty") spaces in an aquifer. The quantity of water that an aquifer can hold in storage is determined by its porosity.

Precipitation The falling of water in liquid or solid form that occurs when the atmosphere becomes saturated with water vapor.

Radioactive tracer A radioactive isotope used to track or monitor the movement and pathway of water.

Radioisotope (Radionuclide) An unstable isotope of an element that decays or disintegrates spontaneously, thereby emitting radiation.

Raindrop The form that water attains as it travels in the atmosphere.

Rainfall A form of precipitation, that is, the quantity or measure of water discharged from the atmosphere within a given time period.

Recharge The addition of water to the saturated zone, either naturally (by rainfall, precipitation, or runoff) or artificially (by spreading zones or injection).

Relative humidity (RH) The actual volume of water vapor in a given volume of air divided by the amount that would be present if the air were saturated at the same temperature.

Residence time The amount of time that water resides within its source area, aquifer, watercourse, or water body before moving to another phase of the hydrologic cycle.

Runoff The portion of precipitation that eventually appears in surface watercourses or water bodies.

Salinity The concentration of total dissolved solids (TDS) in water or, more specifically, the total concentration of dissolved minerals or inorganic salts in water.

Soil moisture The quantity (volume) of water occupying a given volume of soil, expressed as a percentage.

Solute An organic or inorganic constituent dissolved within a solvent.

Stable isotope An isotope that does not undergo radioactive decay.

Stream A conduit in the water cycle, with a current confined within a bed and stream banks that acts as a mechanism for groundwater recharge or discharge and also serves as a corridor for fish and wildlife migration.

Tracer A material or a substance that is introduced into a chemical, biological, or physical medium and used to track or follow a travel or flow path and/or determine the travel time or mean velocity.

Unsaturated zone The area below the ground where the void spaces are filled with a mixture of water under pressure less than atmospheric, which includes water held by capillarity and air (gases) under atmospheric pressure.

Vapor or moisture The gaseous state of water.

Introduction

Freshwater is extremely essential for human survival. Since the last century, phenomenal growth in freshwater use has been observed worldwide. With the dramatic increase in the world's population, a plethora of water-related challenges are raised today in several regions. Each region has its unique problems of quantity and quality of water depending on its geographic, climatic, geologic and socio-economic conditions (Ansari et al., 2016a). With the advent of global warming and climate change, the rainfall pattern is likely to change worldwide and will almost certainly have a negative impact on most of the freshwater resources of the region. Many modeling studies have postulated that by 2050, the distribution of freshwater around the world is approaching a paradigm shift (Alcamo et al., 2007). The large-scale exploitation of groundwater and surface water to meet the growing demands has caused the depletion and contamination of the water resources. This has already affected the lives of millions of people in many regions (Rajaveni et al., 2016; Bhanja et al., 2017; Noble and Ansari, 2019; Ansari et al., 2019). In recent decades, the growing need for freshwater for drinking, domestic use, irrigation and industries, combined with the increasing scarcity of water have been recognized as major challenges for sustainable development. This situation has caused conflicts, social unrest and changes in migration patterns.

The establishment of the Sustainable Development Goal (SDG 6) "Guaranteeing the availability and sustainable management of freshwater and sanitation for all", reflects the increased attention on water and sanitation issues in the global political agenda. To maximize its scope, the objective focuses on all aspects of the water cycle: water, sanitation and health (WASH); water resources management and efficient use of water; wastewater management; water quality and protection of freshwater ecosystems. Therefore, a comprehensive understanding of freshwater resources is necessary for their coherent and prudent management and for the sustainable resource development, which can be acquired through scientific research efforts. In this regard, isotopic data along with hydrochemical data, provides one of the important tools for achieving the goal.

With the development of sophisticated instruments to accurately measure the isotopes of hydrogen and oxygen in water, the introduction of isotope hydrology tools (around 1950) to solve hydrological problems was made, which became one of the most useful modern tools for hydrological assessment. Since then, it has been applied to solve a wide range of problems related to water (surface and groundwater) and environmental studies (atmospheric circulation, climatology and ecology) and is currently a well-established scientific discipline.

Application of isotope hydrology

Isotope hydrology techniques constitute the most promising modern tools for providing critical hydrologic information that sometimes cannot be obtained with other conventional techniques. Its applications include tracing the evolution of the water mass from its beginning in the form of precipitation, through its infiltration below the surface (recharge processes), and finally its manifestation in an aquifer. In addition to this, these techniques can also be used to trace the origin of solutes in groundwater. Isotopic techniques employed to study the different aspects related to water resources management are shown in Table 1.

Different types of isotopes used for hydrological studies

Applications of isotopes in hydrology are based on the general concept of "tracing", in which either artificial radioisotopes (e.g., ^{82}Br , ^{198}Au , ^3H , ^{137}Cs , etc.) are intentionally introduced or naturally occurring environmental stable isotopes (e.g., ^2H , ^{18}O , ^{13}C , ^{34}S , ^{15}N , ^{11}B , ^{87}Sr) or environmental radioactive isotopes (^3H , ^{14}C , ^{36}Cl , ^{222}Rn , ^{226}Ra , etc.) are used (Table 2). Environmental isotopes (radioactive or stable) clearly have the advantage over injected (artificial) tracers because they facilitate the study of various hydrological processes on a much larger spatial and temporal scale due to their natural distribution in a system. The use of artificial tracers is generally effective for local and site-specific applications.

Principles of isotope hydrology

Isotopic fractionation

The application of stable isotopes for the evaluation of hydrological processes is based on the understanding of variations in the isotopic composition of precipitation and surface waters (Clark and Fritz, 1997; Kumar et al., 2010a; Ansari et al., 2018, 2020). At each stage of the hydrological cycle, a small change is recorded by natural physical processes that have resulted in a difference

Table 1 Application of isotope hydrology techniques in various fields.

<i>Surface water</i>	<i>Ground water</i>	<i>Meteorology</i>
Hydrographs separation	Soil moisture variation, movement and recharge	Variability of environmental conditions/climate change
River discharge measurements	Occurrence and recharge mechanism	Movement of clouds and variability in precipitation
Dynamics of lakes and reservoirs	Groundwater flow velocity and direction	Environmental pollution and mechanisms
Water balance	Identification of recharge sources and areas of deeper aquifers and springs	Prediction of arrival and retreat of monsoon
Leakage through dams, seepage losses from irrigation channels	Interconnections between groundwater bodies	
Sedimentation rate, soil erosion rate	Mixing and distribution	
Evaporation/evapotranspiration	Effectiveness of artificial recharge measures	
Surface water and groundwater interaction, sea water intrusion	Data on lithology, porosity, permeability, hydraulic conductivity, transmissivity of aquifers	
Sources and tracing of pollutants	Pollution source and mechanism, groundwater salinization	
Snow and glacial melt runoff	Groundwater dating, paleowaters, infiltration rate, rock-water interaction, geothermal investigations	

Table 2 Isotopes commonly used for different applications in hydrology.

<i>Environmental stable isotopes</i>			
<i>Isotope</i>	<i>Ratio</i>	<i>Reference (ppm)</i>	<i>Application in hydrology</i>
^2H	$^2\text{H}/^1\text{H}$	VSMOW (155)	Source and origin of water, identification of recharge area, surface water-groundwater interactions, groundwater salinization, inter aquifer connection, recycling of irrigation water, geothermal studies
^{13}C	$^{13}\text{C}/^{12}\text{C}$	VPDB	Source of carbonates, groundwater dynamics, rock-water interactions, identification of pollution and groundwater dating (^{14}C) models
^{15}N	$^{15}\text{N}/^{14}\text{N}$	Air N_2 (3677)	Source of pollution, origin of nitrates, microbial denitrification processes
^{18}O	$^{18}\text{O}/^{16}\text{O}$	VSMOW (2005)	Source and origin of water, identification of recharge area, surface water-groundwater interactions, groundwater salinization, inter aquifer connections, recycling of irrigation water, geothermal studies
^{34}S	$^{34}\text{S}/^{32}\text{S}$	CDT	Origin of salinity, identification of pollution sources, redox condition of aquifer, geothermal water investigations
^{37}Cl	$^{37}\text{Cl}/^{35}\text{Cl}$	SMOC (0.324)	Source of pollution, sources of salinity
^{87}Sr	$^{87}\text{Sr}/^{86}\text{Sr}$	USGS <i>Tridacna</i> ,	Provenance of water
^{11}B	$^{11}\text{B}/^{10}\text{B}$	NBS 951—(sodium borate)	Source of pollution/salinity
^{81}Br	$^{81}\text{Br}/^{79}\text{Br}$	SMOB	Origin and evolution of groundwater
^3He	$^3\text{He}/^4\text{He}$	Atmospheric He	Ages of young groundwater
Environmental radioisotopes			
Isotope	Half-life (years)	Type of radiation	Applications in hydrology
^3H	12.3	B	Young groundwater dating, identification of modern recharge, groundwater movement, infiltration rate in unsaturated zones
^{14}C	5730	B	Old groundwater dating, groundwater movement, identification of paleowaters
^{36}Cl	3.1×10^5	B	Very old groundwater dating
^{137}Cs	30	Γ	Sedimentation/deposition rate in watershed, lake, reservoir, water courses etc., estimation of erosion rates
^{222}Rn	3.8 days	α	Surface water-groundwater interaction
^{226}Rn	1600	α	Sub-marine groundwater discharge
^{234}U	246,000	α	Groundwater dynamics and weathering processes
^{39}Ar	269	B	Dating of groundwater
Artificial radioisotopes			
Isotope	Half-life	Chemical from	Applications in hydrology
^3H	12.3 year	HTO	Groundwater recharge rate and flow direction
^{60}Co	5.3 year	$\text{K}_3[\text{Co}(\text{CN})_6]$	Groundwater recharge rate, canal and river flow rate
^{82}Br	36 h	NH_4Br	Groundwater velocity, effluent dispersion
^{198}Au	2.7 day	HAuCl_3	Seepage entry and exit points in dams
^{131}I	8.04 day	I^-	Canal and river flow rate, measurement of aquifer parameters (velocity, hydraulic conductivity, porosity, transmissivity)
^{51}Cr	27.7 day	EDTA complex	Canal and river flow rate

in the isotopic composition in water that is as unique as a fingerprint (Clark and Fritz, 1997). The important processes that are responsible for these variations in the stable isotopic composition of water are the isotopic fractionation that occurs during physical and chemical processes. Evaporation of water and condensation of vapor are examples of the physical process that cause isotopic fractionation, while chemical fractionation occurs due to chemical bonding, because the heavy isotopes have stronger bonds than those of light isotopes.

Fractionation can be caused during equilibrium and non-equilibrium conditions. Evaporation occurs mainly under non-equilibrium conditions, while condensation is an equilibrium process. When seawater evaporates, the lighter isotopes of oxygen and hydrogen are preferably converted to vapor, while during the condensation process, the heavier isotopes are preferably condensed, leaving the residual vapor more and more depleted in heavy isotopes. Both these physical processes cause a variation in the isotopic composition of the water molecules. Fig. 1 shows the cooling of the precipitating air mass with an initial isotopic composition of vapor ($\delta^{18}\text{O} = -10\text{‰}$), the same as that of fresh evaporate generated in the ocean. The difference between the vapor (red) and condensate (blue) curves in Fig. 1 shows an enrichment of about 10‰ when the condensate turns into a liquid in the vapor reservoir due to the preferential condensation of heavy isotopes. As the rainout process continues with the decreasing residual vapor fraction (f), this preferential removal of heavy isotopes continues, causing gradual depletion of heavy isotopes in the vapor and the condensate that is formed. The $\delta^{18}\text{O}$ content of different components of the hydrological cycle are shown in Fig. 2.

Isotopic fractionation generally brings small differences in the isotopic composition and the rare isotopes abundance of these elements is low. Therefore, the absolute abundance of isotopes is generally not measured. Instead, the measurements are reported in parts per thousand (‰ ; per mil) as delta (δ) notation, which is the deviation from the standard reference, V-SMOW (Vienna-Standard Mean Ocean Water). The δ values are calculated using (Coplen, 1996):

Fig. 1 Isotopic values of condensate (precipitating air mass) and vapor depleting as per the Rayleigh model. Modified based on Clark ID and Fritz P (1997) *Environmental Isotopes in Hydrogeology*. Boca Raton, FL: Lewis Publishers.

Fig. 2 $\delta^{18}\text{O}$ in different components of the hydrological cycle.

$$\delta(\text{‰}) = \left(\frac{R_x}{R_s} - 1 \right) \times 1000 \quad (1)$$

where R denotes the ratio of heavy to light isotope (e.g., $\frac{^2\text{H}}{^1\text{H}}$ or $\frac{^{18}\text{O}}{^{16}\text{O}}$) and R_x and R_s are the ratios in the sample and standard respectively. The isotopic compositions of the water samples are measured using an isotope ratio mass spectrometer (IRMS). Over the past decade, many significant advances have been made in the field of isotopes measurement. Now, inexpensive laser absorption spectrometers (Crosson et al., 2002), satellite based measurements of the isotopic composition of moisture (Frankenberg et al., 2009), and ground based remote sensing using spectra (Rokotyan et al., 2014) are available to perform the same function. At the same time, significant progress has been noted in numerical modeling through widespread use of the isotope enabled General Circulation model (Risi et al., 2012) and limited area models (Blossey et al., 2010). The range of isotopes ($\delta^{18}\text{O}$) of different hydrological bodies is illustrated in Fig. 3.

Global meteoric water line (GMWL)

The isotopic composition of precipitation measured worldwide has shown that stable isotopes ($\delta^{18}\text{O}$ and $\delta^2\text{H}$) values fall along a straight line on a $\delta^{18}\text{O}$ - $\delta^2\text{H}$ plot (Craig, 1961). This best fit line, termed as the global meteoric water line (GMWL), is given as:

$$\delta^2\text{H} = 8\delta^{18}\text{O} + 10 \text{ (‰VSMOW)} \quad (2)$$

Rozanski et al. (1993) further refined the Craig's GMWL equation by adding precision to it based on isotope data of precipitation from 219 sites (Gat, 1981) established by the IAEA since 1953 under the GNIP (Global Network of Isotopes in Precipitation) program. The refined relationship between $\delta^{18}\text{O}$ and $\delta^2\text{H}$ in global precipitation is given as:

$$\delta^2\text{H} = 8.17 (\pm 0.07) \delta^{18}\text{O} + 11.27 (\pm 0.65) \text{ (‰VSMOW)} \quad (3)$$

Various effects, such as evaporation of source water, recycling of moisture, and secondary evaporation, can cause deviations of the precipitation isotopes of any location from the GMWL (Breitenbach et al., 2010; Chakraborty et al., 2016; Kumar et al., 2010b), which is described as the Local Meteoric Water Line (LMWL) for that location (Table 3) and $\delta^{18}\text{O}$ - $\delta^2\text{H}$ plots in Fig. 4.

The deviation in the slope and intercept of the GMWL provides information regarding non-equilibrium processes caused during evapotranspiration, precipitation and moisture transport.

Fig. 3 Isotope ($\delta^{18}\text{O}$) range in the water cycle. Common values are marked with black a line. Modified based on Koniger P (2003) Tracerhydrologische Ansatz zur Bestimmung der Grundwasser-Neubildung. *Freiburger Schriften zur Hydrologie* 16: 89 p., Freiburg.; Clark ID and Fritz P (1997) *Environmental Isotopes in Hydrogeology*. Boca Raton, FL: Lewis Publishers.

Table 3 Regional meteoric water line of different region.

Region	Meteoric line (‰)	References
Global meteoric line	$\delta^2\text{H} = 8\delta^{18}\text{O} + 10$	Craig (1961)
Northern hemisphere (continental)	$\delta^2\text{H} = (8.1 \pm 1)\delta^{18}\text{O} + (11 \pm 1)$	Dansgaard (1964)
Mediterranean or Middle-East	$\delta^2\text{H} = 8\delta^{18}\text{O} + 22$	Gat (1971)
Northeastern Brazil	$\delta^2\text{H} = 6.4\delta^{18}\text{O} + 5.5$	Salati et al. (1980)
Northern Chile	$\delta^2\text{H} = 7.9\delta^{18}\text{O} + 9.5$	Fritz et al. (1979)
Tropical island	$\delta^2\text{H} = (4.6 \pm 0.4)\delta^{18}\text{O} + (0.1 \pm 1.6)$	Dansgaard (1964)
India	$\delta^2\text{H} = 7.93\delta^{18}\text{O} + 9.94$	Kumar et al. (2010a)
East India	$\delta^2\text{H} = 7.86\delta^{18}\text{O} + 8.81$	Ansari et al. (2020)
Thailand	$\delta^2\text{H} = 8\delta^{18}\text{O} + 9.4$	Wei et al. (2018)
Australia	$\delta^2\text{H} = 8.3\delta^{18}\text{O} + 14.1$	Hollins et al. (2018)

Oxygen-17 (^{17}O)-excess

Researchers are currently using a triple isotopic composition of oxygen ($\delta^{17}\text{O}$ and $\delta^{18}\text{O}$) in meteoric water and marine water vapor for climatological and groundwater studies (Landais et al., 2006; Uemura et al., 2010). The $\Delta^{17}\text{O}$ anomaly is defined as ^{17}O excess by Barkan and Luz (2007) as;

$$\Delta^{17}\text{O} = \delta^{17}\text{O} - 0.528 \delta^{18}\text{O} \quad (4)$$

where δ' is the modified δ notation and is defined analogously for ^{17}O . The $\delta^{17}\text{O} = 1n(\delta^{17}\text{O} + 1)$ and $\delta^{18}\text{O} = 1n(\delta^{18}\text{O} + 1)$, and 0.528 is the slope of GMWL. Since the magnitude of $\Delta^{17}\text{O}$ is very small, it was multiplied by 10^6 and reported as per meg rather than per mil with respect to VSMOW.

Deuterium excess (d-excess)

The $\delta^{18}\text{O}$ and $\delta^2\text{H}$ relation has been further described by another parameter, known as deuterium excess (d-excess) by Dansgaard (1964) and that is defined as:

$$\text{d-excess} = \delta^2\text{H} - 8 \delta^{18}\text{O} \quad (5)$$

It is used as a measure of the kinetic fractionation that occurs under non-equilibrium conditions, such as the evaporation of vapor at the sea surface (Zhou and Li, 2018). It also indicates the thermal condition and the equilibrium situation of vapor during the formation of air mass over the sea and the continent. It retains the signature of the climatic conditions under which rain forms, such as relative humidity (RH), temperature, sea surface temperature (SST), and supersaturated conditions (Pfahl and Sodemann, 2014). d-excess values can be used to understand the environmental conditions of moisture sources and is mainly influenced by the RH, SST, air temperature and sea surface isotopic composition at the moisture source region. It can also be used to understand the recycling of moisture over the continents and in the ocean (Rahul et al., 2018).

The value of d-excess is inversely correlated to RH and this is due to the molecular diffusion from the sea surface into the atmosphere at the air-sea interface, which is controlled by wind dynamics and temperature (Benetti et al., 2014; Rahul et al., 2018).

Fig.4 A graphic illustration of different water bodies falling along the global meteoric water line (GMWL).

d-excess is also positively correlated with sea surface temperature. That is because of the kinetic and equilibrium fractionation during phase changes (Munksgaard et al., 2015).

During the dry climatic conditions, the kinetic fractionation becomes robust because of the high evaporation. This is the reason why the residual water has lower d-excess, while the vapor produced has higher d-excess values and the precipitation from that vapor also has higher d-excess (Clark and Fritz, 1997; Kendall and McDonnell, 1998). During light precipitation, falling raindrops evaporate that result in lower d-excess in rainwater (Gupta and Deshpande, 2005).

The d-excess value is generally conserved in water vapor and the rain it produces will have the same values. However, it can change due to the sub-cloud evaporation or re-equilibration caused by the surrounding vapor when it descends to the surface (Balagizi et al., 2018). Therefore, d-excess acts as proxy and can be used to evaluate the climate change and meteorological conditions of any region. The average d-excess is 10‰ on the global scale.

Stable isotope effects

The isotopic composition ($\delta^{18}\text{O}$, $\delta^2\text{H}$) of precipitation has a unique characteristic, which varies with time and region. The isotopic signature of the precipitation depends on many factors or parameters such as temperature, relative humidity, isotopic values of moisture source, etc. When these factors are considered, the isotopic signatures provide information on the source and origin of moisture, precipitation and groundwater, as well as the climatic conditions at the time of recharge. Dansgaard (1964) observed that four important drivers for the isotopic variability in precipitation are distance from coast, altitude, rainfall amount, and latitude. These drivers depend principally on the temperature.

Altitude effects

The decrease in the isotopic composition of precipitation with increasing altitude is called altitude effects. This normally occurs during the orographic uplifting of humid air mass on the windward side of the mountain (Fig. 2). This depletion of the isotopic

composition may be due to the decrease in cloud temperature and the vapor saturation pressure with increasing elevation. A depletion of -0.15 to -0.6‰ in $\delta^{18}\text{O}$ has been observed per 100 m increase in elevation. The signature of altitude effects can be seen in groundwater in mountainous region and is used to distinguish its recharge at higher altitude (Kumar et al., 2012 & 2014). Therefore, it is useful for the hydrogeological studies.

Continental effects

The depletion of the isotopic ratio of precipitation with the increasing distance from the coast is called as continental effect. The continental effect is observed in precipitation, i.e. the precipitation is depleted in the heavier isotope of water molecules as we move away from the coastal parts. Since the oceans are the main source of moisture that causes most of the precipitation around the world, and as the moisture moves from its region of origin towards the interior of the continent, the rain out process depletes the precipitation in $\delta^{18}\text{O}$ and $\delta^2\text{H}$ with respect to the distance from the coast (Fig. 2). In addition, the depleted terrestrial moisture can be recycled, again depleting the isotopic ratios. As a result, coastal precipitation is isotopically enriched, while the inland regions receive isotopically depleted precipitation with strong seasonal differences. On average, there is approximately -2‰ depletion in $\delta^{18}\text{O}$ per 1000 km from the seacoast (Rozanski et al., 1993). Groundwater has a correspondingly depleted isotopic ratio as the distance from the coast is increased.

Amount effects

An area with a high amount of precipitation can sometimes have a significantly depleted isotopic composition. This amount effect is particularly observed in the region that is affected by the ITCZ and in hurricanes, as well as, (sometimes) in the convective precipitation regimes. The highly depleted isotopic ratio in heavy precipitation is caused by poor rainwater equilibration, which arises due to large rain droplets and high RH below the convective clouds, downdraughts and recycling of precipitation. This is also caused between the consecutive rain bands (Lawrence et al., 1998).

Temperature effects

The isotope ratios of precipitation are well correlated with the surface temperature. Dansgaard (1964) established its relation as:

$$\delta^{18}\text{O} = 0.62 T - 15.25 (\text{‰}) \quad (6)$$

This relationship between the stable isotopes and the temperature is currently used as a tool for the paleoclimate assessment of the region. The isotopic ratio of precipitation also depends on the temperature at which seawater evaporates. Seasonal variations in the isotopic ratios of local precipitation are caused by temperature fluctuations. The precipitation occurring during winter is isotopically depleted relative to the precipitation during the summer. In the geological past, when the climate was considerably different from today, the isotopic signatures of groundwater recharged at that time were very different from that of modern groundwater and precipitation. Fig. 5 illustrate how temperature influences the isotopic composition of any region.

Fig. 5 Relation between weighted average $\delta^{18}\text{O}$ of precipitation and the average air temperature for 325 GNIP stations. Modified based on Gourey LL, Groening M, and Aggarwal PK (2005) Stable oxygen and hydrogen isotopes in precipitation. In: Aggarwal PK, Gat JR, and Froehlich KFO (eds.) *Isotopes in the Water Cycle: Past, Present and Future of a Developing Science*, pp. 39–53. Springer.

Furthermore, the latitudinal depletion of isotopic ratios (latitude effects) are also caused by temperature-dependent isotopic fractionation (Fig. 5). In semi-arid and arid regions, due to the low RH and low precipitation, the falling raindrops undergo evaporation, resulting in enrichment in heavy isotopes (evaporation effect). In addition, due to evaporation, surface waters (ponds, lake, rivers) are isotopically enriched.

Different environmental and radioactive isotopes for water resources development

Strontium-87 (^{87}Sr) isotope

Strontium is a minor constituent of groundwater. Strontium has four stable isotopes: ^{84}Sr , ^{86}Sr , ^{87}Sr and ^{88}Sr . Of these, only $^{87}\text{Sr}/^{86}\text{Sr}$ ratios are generally used for hydrological applications. The concentration of strontium in precipitation is generally low and can vary by two orders of magnitude from 2×10^{-3} to 3×10^{-1} mg/L. The much higher concentration in groundwater may be due to the dissolution of Sr-bearing minerals. No natural fractionation of stable strontium isotopes has been observed during the natural processes. This property makes the strontium isotopic ratio a reliable tool for evaluating the mixing of groundwater and for tracing water-rock interactions (Clark and Fritz, 1997). The $^{87}\text{Sr}/^{86}\text{Sr}$ ratios are measured using thermal ionization mass spectrometry (TIMS).

Boron-11 (^{11}B) isotope

Geochemical indicators like Br/Cl, B/Cl, etc., along with ^{11}B isotopes can be used to identify the source of salinity. The content of B changes as a result of water-rock interactions, mixing with waters of different origin and by the addition of contaminants. Boron has two stable isotopes, ^{10}B and ^{11}B . ^{11}B is measured using the positive ion thermal ionization mass spectrometry (TIMS). Values are reported in δ notation with respect to NBS951 boric acid standard. The large isotopic variation (90‰) of B, which is recognized in natural reservoirs, makes $\delta^{11}\text{B}$ a potential tool for tracing the origin of dissolved salts in groundwater.

Chlorine-37 ($\delta^{37}\text{Cl}$) isotope

This radioisotope is used to identify the source of Cl^- in groundwater, the mixing of fluids, and the rock-water interaction in an aquifer. $\delta^{37}\text{Cl}$ has been proven to be a useful tool for identifying sources of solute and for distinguishing solute transport mechanisms (Godon et al., 2004). The separation of ^{35}Cl and ^{37}Cl takes place by diffusion processes in argillaceous formations due to higher mobility of ^{35}Cl than that of ^{37}Cl , and this causes a depletion of ^{37}Cl in groundwater with increasing distance from a Cl^- source. Therefore, the $\delta^{37}\text{Cl}$ content of modern seawater is expected to differ from those of paleo seawater, which has been modified by diffusion processes in argillaceous sediments. Therefore, the difference in $\delta^{37}\text{Cl}$ could allow distinction of salinity from different origins and provide more information on seawater intrusions in a confined aquifer system. The fractionation of chlorine isotopes occurs due to the physical processes such as salt precipitation, brine evaporation, ion filtration, ion exchange and diffusion.

Bromine-81 ($\delta^{81}\text{Br}$) isotope

The use of bromine-81 to assess the origin and evolution of groundwater is still in its early stage, and only a few researches presently exist on this topic, although considerable work has been done on its natural variation in other parts of the world. Shouakar-stash et al. (2007) measured the $\delta^{81}\text{Br}$ isotope of groundwater samples from the Siberian platform, Russia and assessed the sources of various saline waters, including halite dissolution and seawater evaporation. This work showed its potential use in investigation of source and evolution processes of groundwater. Hence, this isotope can be used to understand the geochemical evolution of groundwater.

Nitrogen-15 ($\delta^{15}\text{N}$) isotope

The probable sources of nitrate/ammonia in groundwater are from mineral or organic fertilizers used for agriculture, from sewage/manure systems, and from waste dumps. The environmental isotopes tracers can be used to identify the origin of nitrate pollutants and solutes. Stable isotopes of nitrate can be used to distinguish the potential source of fertilizer (organic and inorganic) or mineralization of a nitrogen bearing substance within soil and precipitation. In groundwater, the origin of nitrate and ammonia can be identified using the nitrate isotope ($\delta^{15}\text{N}$). However, the advancement in analytical methods now allows the determination of $\delta^{18}\text{O}$ -nitrate. Both, $\delta^{15}\text{N}$ -nitrate and $\delta^{18}\text{O}$ -nitrate can be used together to discriminate the source of atmospheric nitrate and nitrate from fertilizer. Typical ranges of different sources of nitrate are shown in Fig. 6.

Sulfur-34 ($\delta^{34}\text{S}$) isotopes

Sulfate is one of the dissolved constituents of the groundwater and surface water. Identification of its sources and biogeochemical evolution is important for water resource managers. Sulfate may cause hardness of water. Hence, the identification of the source of

Fig. 6 Typical range of $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ of nitrate of different sources. Modified based on Kendall C and McDonnell JJ (1998) *Isotope Tracers in Catchment Hydrology*. Amsterdam: Elsevier, p. 839.; Mayer B (2005) Assessing sources and transformation of sulphate and nitrate in the hydrosphere using isotope techniques. In: Aggarwal PK, Gat JR, and Froehlich KFO (eds.) *Isotopes in the Water Cycle: Past, Present and Future of a Developing Science*, pp. 67–89. Springer.

sulfate is essential for water resource development. The stable isotopic composition of dissolved sulfate ($\delta^{34}\text{S}$) is often used to identify the source of sulfates. In addition, the spatial or temporal variability of sulfate concentration with respect to changing isotope ratios may divulge the biogeochemical processes controlling the occurrence of sulfate in the surface and sub-surface water bodies. Sulfur has four isotopes (^{32}S , ^{33}S , ^{34}S and ^{36}S), and due to their abundances, ^{34}S and ^{32}S are normally used for the measurement using the isotope ratio mass spectrometer (IRMS). The isotopic composition of sulfur is reported as $\delta^{34}\text{S}$, the ratio of $^{34}\text{S}/^{32}\text{S}$ in per mil (‰) relative to the V-CDT (Canon Diablo meteorite) standard. The $\delta^{34}\text{S}$ value ranges from +50‰ to –50‰ in the terrestrial environment. Geological formations (gypsum, evaporites, limestone, shales) that contain primary and secondary sulfide minerals, as well as chemically precipitated sulfate minerals, are the possible sources of sulfate in groundwater. The ranges of different sources of sulfate in a hydrological system are shown in Fig. 7.

Helium (He) isotopes

The stable isotopes of the noble gas helium (^3He , ^4He) offer a relatively new tool in isotope geochemistry. The solubility of atmospheric noble gases in water depends on the temperature (solubility increases with temperature) and their concentration in air. ^3He ,

Fig. 7 Typical ranges of $\delta^{34}\text{S}$ and $\delta^{18}\text{O}$ values of sulfate. Modified based on Mayer B (2005) Assessing sources and transformation of sulphate and nitrate in the hydrosphere using isotope techniques. In: Aggarwal PK, Gat JR, and Froehlich KFO (eds.) *Isotopes in the Water Cycle: Past, Present and Future of a Developing Science*, pp. 67–89. Springer.

the daughter product of tritium decay, provides the age of young groundwater without knowing the tritium input function. ^4He in groundwater is used for dating old groundwater, as well as for understanding the possible mixing of waters of different ages ranging from 10^4 to 10^8 years (Clark and Fritz, 1997; Solomon and Cook, 2000).

Stable carbon-13/12 isotopes

Carbon, a ubiquitous element of the biosphere and hydrosphere, has two environmental stable isotopes (^{12}C , ^{13}C). Initially, carbon isotope ratios were used to reconstruct the palaeotemperature scale using marine carbonates. The chemistry of groundwater is strongly dependent on carbonate geochemistry (Clark and Fritz, 1997) and analyses of $\delta^{13}\text{C}$ of carbonate species is used to understand the carbonate geochemistry and geochemical evolution of groundwater. $\delta^{13}\text{C}$ is also essential for the quantification of the initial content of ^{14}C for dating purposes using ^{14}C . Carbon isotopes in geothermal systems have been used for gaining insights into reservoir conditions and for the geothermometry of such waters. They are also valuable in tracing the sources of contaminants to groundwater (Clark and Fritz, 1997; Bird et al., 2020). The ranges of $\delta^{13}\text{C}$ composition of the major sources of carbon are shown in Fig. 8.

Tritium (^3H)

Tritium is a radioactive isotope of hydrogen with a half-life of 4500 ± 8 days (Lucas and Unterweger, 2000), which decays into ^3He by beta (β) emission. Environmental tritium is a natural isotope that is formed in the upper atmosphere (stratosphere) by the interaction of cosmic rays with nitrogen (N) atoms, at an average rate of $2500 \text{ atoms m}^{-2} \text{ s}^{-1}$ (Masarik and Beer, 2009). In addition, it is also generated by various nuclear based anthropogenic activities like nuclear weapons explosions, bombardment of ^6Li in the reactors, etc. The main source of tritium in the atmosphere comes from atmospheric thermonuclear tests between the years 1953 and 1963. In 1963, tritium in precipitation reached the maximum level of several thousands of Tritium units (TU) (approximately 10,000 TU), which was 2–8 TU before nuclear tests (Michel, 2005). One TU is equivalent to one tritium atom per 10^{18} hydrogen atoms, corresponding to 0.120 Bq/L at standard temperature and pressure. Most of the environmental tritium (around 55%) is produced in the stratosphere and it has been estimated that $5\text{--}9 \times 10^5$ TU of atmospheric tritium resides in the vapor of the stratosphere (Fouere et al., 2006). Tritium is highly mobile and is easily exchanges with water molecules or hydrogen. Therefore, it is available everywhere in the hydrological systems. It is a useful environmental tracer for assessing the hydrological system, particularly in the dating of groundwater (Morgenstern and Daughney, 2012). It is an element of the water molecule (HTO) and has been used for

Fig. 8 The range of $\delta^{13}\text{C}$ composition of the major sources of carbon. Modified based on Bird MI, Haig J, Hadeen X, et al. (2020) Stable isotope proxy records in tropical terrestrial environments. *Palaeogeography, Palaeoclimatology, Palaeoecology* 538: 109445.

the past five decades as a tracer for the understanding of hydrological systems. The anthropogenic tritium that was released into the atmosphere during the nuclear tests is used to distinguish between modern groundwater recharge and pre-nuclear test recharge (Yangui et al., 2012). Current advanced models, particularly lumped parameter modeling, are used to quantify the mean transit time of groundwater, and are used to calibrate and validate other groundwater models such as the solute transport model, the 3D-GW flow model, etc. (Zuber et al., 2011). Tritium is also used to calculate recharge rates of groundwater and its renewability (Kumar et al., 2008), residence time as well as velocity and directions of groundwater flow (Sawdoni et al., 2000; Ansari et al., 2014, 2017).

In addition, tritium is extensively used in the study of the surface water system, such as lakes, rivers and streams (Michel, 2004). Time series tritium data of a river can be used to identify the river characteristic, whether it is the influent river or the effluent river.

The normal vertical distribution of tritium and deuterium in the atmosphere is shown in the Fig. 9. It is observed that $\delta^2\text{H}$ content gradually decreases up to the tropopause and then increases in the stratosphere up to 40 km (Johnson et al., 2001), while tritium increases gradually with increasing altitude in the atmosphere up to the tropopause (Zahn et al., 1998).

Age dating using tritium

Tritium decays to the noble gas ^3He . Since the absolute activity of ^3H has decreased over the past several decades and has almost reached the level of natural input, the combined use of $^3\text{H}/^3\text{He}$ helps to define groundwater ages based on the ratio of both isotopes. The age dating method using $^3\text{H}/^3\text{He}$ is based on the equation given below:

$$T = \frac{1}{\lambda} \ln \left(\frac{^3\text{He}_{\text{trit}}}{^3\text{H} + 1} \right) \quad (7)$$

where T is age of groundwater, λ is the tritium decay constant, and ^3He is the tritiogenic helium derived from the decay of tritium only.

The dating of groundwater using the $^3\text{He}/^3\text{H}$ ratio is less sensitive for older waters and requires precise determinations of excess air applicable for the close systems at the groundwater surface (Solomon and Cook, 2000). This method is not applicable for the groundwater nearby major fault zones, geothermal fields or geologically young igneous rocks since the concentration of geogenic sources may exceed the ^3He derived from tritium decay by an order of magnitude.

Radioactive carbon (^{14}C) isotope

Carbon-14 is a radioisotope of carbon having a long half-life of 5730 years. It is naturally produced in the upper atmosphere by the collision of cosmic ray produced neutrons with common nitrogen. These ^{14}C atoms are oxidized to carbon dioxide and enter the troposphere and participate in the biological and hydrological carbon cycle. By the biological action such as root respiration and decomposition of plant material, carbon dioxide enters into the soil. Rain dissolves small amounts of atmospheric carbon dioxide. Significantly, more carbon dioxide is added to water percolating through the soil layer, since soil air contains 100 times more carbon

Fig. 9 Generalized vertical distribution of $\delta^2\text{H}$ and tritium (^3H) in the atmospheric moisture. Modified based on Rozanski K (2005). Isotopes in atmospheric moisture. In: Aggarwal PK, Gat JR, and Froehlich KFO (eds.). *Isotopes in the Water Cycle: Past, Present and Future of a Developing Science*, pp. 291–302. Springer.

dioxide than free air. Once water reaches the saturated zone, it is sealed from the atmosphere and its ^{14}C content decays, thus forming the basis for groundwater dating (Clark and Fritz, 1997). It decays according to:

$$a_t = ca_0 e^{-\lambda T} \quad (8)$$

$$T = -\frac{1}{\lambda} \ln \left(\frac{a_t}{ca_0} \right) \quad (9)$$

where, $\lambda = 1.2097 \times 10^{-4}$ is the decay constant, c is the dilution factor, a_t is the ^{14}C activity at time t , and a_0 is the initial ^{14}C activity (Geyh and Schleicher, 1990). The ^{14}C activities are expressed as pmC (percent modern carbon). The modern atmospheric carbon-14 (pre-nuclear test) content is 100 pmC corresponding to 13.56 dpm/gC in the year 1950 AD (Stuiver and Polach, 1977). The ^{14}C in the water samples is measured using a liquid scintillation counter or using an accelerator mass spectrometer. When the groundwater gets isolated from the atmosphere, the decay of ^{14}C in dissolved organic and inorganic carbon is used for dating the groundwater. The time at which groundwater became isolated from the atmosphere can be estimated using the ratio of initial and actual ^{14}C activities, a_0 and a_t as per the above equation. There are uncertainties associated with the estimation of initial activities, a_0 , because of potential contamination from post-nuclear detonations (post-1950), paleoclimatic recharge conditions, dilution, change in recharge rate and change from open to closed systems. Therefore, the estimation of a_0 should be done using geochemical adjustment models (Fig.10) such as the Vogel model (Vogel, 1967 and 1970), Tamers model (Tamers, 1967), Pearson model (Ingerson and Pearson, 1964), Eichinger model (Eichinger, 1983), IAEA model (Salem et al., 1980), Evans model (Evans et al., 1979), the Mook model (Mook, 1972, 1976, 1980) and the Fontes and Garnier model (Fontes and Garnier, 1979).

Chlorine-36 (^{36}Cl) isotope

Chlorine-36 is produced in the atmosphere predominantly by cosmic ray spallation of ^{40}Ar and to a lesser extent by the neutron activation of ^{36}Ar and ^{35}Cl . This chlorine-36 is then mixed with the atmospheric chloride (i.e. Cl derived from the ocean) and is deposited on the land surface during rains or snowfalls or as dry aerosols. When groundwater recharge takes place, it carries the ^{36}Cl into the subsurface where the radiometric “clock” is set. It is conservative within the subsurface. Therefore, it rarely retards by adsorption or any geochemical reactions in the subsurface. ^{36}Cl , which has a half-life of 301,000 years, is used for dating water in the age range 100,000 years to 1 million years. However, there are large uncertainties associated with the quantification of age. That is because of the variations in the Cl concentration in groundwater. The presence of evaporites in the catchment and evapotranspiration enrichment in the unsaturated zone, as well as variation in ^{36}Cl , fallout may cause complications.

This technique is also used to delineate the recharge rate of groundwater. The ^{36}Cl in water can be measured using an accelerator mass spectrometer (AMS) (Davis et al., 1983). It was first used to date old groundwater in the Great Artesian Basin, Australia and Milk River aquifer, Canada (Bentley et al., 1986; Phillips et al., 1986).

Fig. 10 Geochemical process (reactions) and a_0 adjustment models.

Krypton-81 (^{81}Kr) isotope

This Krypton-81 isotope, with a long half-life of 229,000 years, is an ideal tracer because of (1) its inertness (non-reactive), (2) being derived only from an atmospheric source, and (3) the absence of any sub-surface source or sink except radioactive decay (Jiang et al., 2012; Matsumoto et al., 2018). The advancement of analytical techniques with high counting efficiency and shorter measurement time has made this tracer useful for dating old groundwater (Aggarwal et al., 2015). For ^{81}Kr analysis, a large volume of water samples of 2000–3000 L is pumped through a vacuum extraction chamber and the gas extracted is transferred to a container. Using preparative gas chromatography, Kr is then extracted from the bulk gas (Lu et al., 2014). The $^{81}\text{Kr}/\text{Kr}$ and $^{85}\text{Kr}/\text{Kr}$ ratios are determined using the Atom Trap Tracer Analysis (ATTA-3) instruments. As per the exponential decay law, the time elapsed since the water was in contact with the atmosphere can be estimated according to:

$$T = -\frac{1}{\lambda} \ln \left(\frac{R_{\text{sample}}}{R_{\text{air}}} \right) \quad (10)$$

where, $\lambda = 3.03 \pm 0.14 \times 10^{-6} \text{ year}^{-1}$ is the ^{81}Kr decay constant and R_{sample} and R_{air} are the $^{81}\text{Kr}/\text{Kr}$ ratios of the samples and modern air ($5.2 \pm 0.6 \times 10^{-13}$) respectively (Du et al., 2003).

Krypton-85 (^{85}Kr) isotope

^{85}Kr is another radioisotope of Kr that may also be used for dating of groundwater, due to its similar nature as that of ^{81}Kr . It has a short half-life ($t_{1/2} = 10.76$ years) and is used for dating groundwater less than 50 years old. It is the fission product of plutonium and uranium. The current specific activity of ^{85}Kr in the atmosphere is about $1.4 \text{ Bq/cm}^3_{\text{STP}}$ corresponding to a ratio of $^{85}\text{Kr}/\text{Kr}_{\text{total}}$ of 2.4×10^{-11} (Winger et al., 2005). The sampling and analytical procedure for the measurement of the $^{85}\text{Kr}/\text{Kr}$ ratio is same as that of $^{81}\text{Kr}/\text{Kr}$. ^{85}Kr is also used to monitor air contamination caused during sampling and gas extraction for the ^{81}Kr and ^{39}Ar dating process (described below) and to determine possible inter-aquifer leakage in the well.

Argon-39 (^{39}Ar) isotope

^{39}Ar is produced in the atmosphere by the interaction of cosmic rays with K and Ar nuclides. The equilibrium activity of Ar in the atmosphere is constant at $1.67 \times 10^{-2} \text{ Bq/m}^3$ of air, which corresponds to a $^{39}\text{Ar}/\text{Ar}$ ratio of $\sim 10^{-15}$ in the atmosphere. Argon-39 has half-life ($t_{1/2}$) of 269 years and is used for dating groundwater that falls between the modern water indicators ($^3\text{H}/^3\text{He}$, CFCs, etc.) and the ^{14}C radiocarbon methods. For ^{39}Ar analysis, a large volume of water samples of 2000–3000 L is pumped through a vacuum extraction chamber and the gas extracted is transferred to a container. Using preparative gas chromatography, Ar is extracted from the bulk gas (Lu et al., 2014). The ^{39}Ar activities are determined using low level gas proportional counters and the results are reported in %modern Ar (Loosli et al., 2000). ^{39}Ar can also be used to evaluate the presence of comparatively modern component (60–1000 years) water in the very old groundwater that cannot be identified using other isotopes, such as ^{85}Kr , ^3H , CFC analysis (Fig. 11).

Fig. 11 Range of age dating using different radioisotopes and other environmental tracers.

Uranium-234/238 isotopes

The $^{234}\text{U}/^{238}\text{U}$ ratio in the groundwater samples can be used to constrain the groundwater dynamics and weathering processes (Clark and Fritz, 1997). A very low $^{234}\text{U}/^{238}\text{U}$ ratio indicates the lack of radioactive equilibrium in waters due to intense weathering as well as slow moving groundwater. A lower ratio is indicative of younger groundwater. In the higher transmissivity wells, there is a weak pattern of increasing activity ratio (AR) with increasing transmissivity.

Radon (^{222}Rn) and radium (^{226}Ra) isotopes

Radium has four natural isotopes, ^{223}Ra , ^{224}Ra , ^{226}Ra , ^{228}Ra and their half-lives are 11.4 days, 3.6 days, 1600 years, and 5.8 years, respectively. ^{226}Ra and ^{223}Ra are the decay products of ^{238}U and ^{235}U , while ^{224}Ra and ^{228}Ra are decay products of ^{232}Th . Radium is released into the groundwater by alpha recoil during the decay of the parent nuclide within the aquifer matrix, desorption from the surface of the rocks, and from dissolution. In surface water, radium isotopes are normally lesser than that of groundwater because of decay and adsorption (Wang et al., 2016). Therefore, this technique is used for evaluating the sub-surface groundwater discharge within the Sea (Liu et al., 2017). The distribution of radium in groundwater is mainly controlled by the chemistry of groundwater and the distribution of their parents' isotopes (U, Th) with the aquifer matrix (solid) (Sherif et al., 2018).

As for radon (^{222}Rn), it is a dissolved gas that is produced by the decay of the parent nuclide (^{226}Ra) present in the water and from alpha recoil during the decay of ^{226}Ra within the solid matrix. Radon sinks within the groundwater either by its radioactive decay or by the loss to the unsaturated zone due to degassing. ^{222}Rn is not absorbed by solids. Therefore, it is highly soluble in water, exactly the opposite of ^{226}Ra . In groundwater, radon variability is large because of the large scale variation in the fracture characteristics of the rock and groundwater flow dynamics (Noble et al., 2015). Owing to its short half-life (3.8 days), radon is indicative for young groundwater. Radon is also used to assess the surface water-groundwater interactions, to delineate the geological structure (faults, lineaments, etc.) (Ansari et al., 2016b) and to evaluate earthquakes.

Lead-210 (^{210}Pb) isotope

Lead (^{210}Pb) has little importance for hydrological applications, although, it is widely used for estimating the accumulation rate of sediments or ice. As ^{222}Rn gas escapes from the earth surface and decays by way of short-living daughters to ^{210}Pb in the atmosphere, after a short time in the air it settles down either by dry or wet precipitation along with snow (to form ice) or sediment in water. Since its half-life is 22.26 years, it can be used to estimate the age of ice and aqueous sediments deposit up to about 100 years.

Modeling of environmental water isotopes

Currently available stable isotope models have proved to be very valuable, both in local and global scales, in understanding and utilizing stable isotopes processes to widely varying degrees. Since the first use of Rayleigh distillation models, research has progressed towards GCMs which have enabled stable isotope processes to be coupled to the model's hydrological cycle.

There are two categories of stable isotope models; namely, Lagrangian and Eulerian, which are fundamentally distinct. The Lagrangian approach evaluates the fractionation of moisture in an air parcel during its transport in space and time, whereas the Eulerian model approaches evaluate isotopic fractionation based on first principles for the whole temporally and spatially discretized model domain. Both approaches are supported by parameterizations of sub-grid scale processes. Although increasingly complex models have been developed in both categories, several intermediate approaches have recently been introduced that combine the advantages of the two families of models, Lagrangian and Eulerian. Some of the important models available are the Lagrangian Rayleigh model, the 2D column model, the 2D advection model, the 3D GCMs and RCMs models, etc. All these available models have provided valuable insight on the climatological interpretation of the stable isotopic signal in many regions of the world.

Conclusions

A better understanding of hydrological systems is important for developing policies and practices for the sustainable management of freshwater resources. Isotope hydrology techniques have provided unmatched insights into the governing processes of the hydrological systems. Environmental isotopic tracers are now the most promising modern tools for providing critical hydrological information that sometimes cannot be obtained with other conventional techniques. The availability of advanced, inexpensive and easy-to-use instruments for measuring different isotopes has made progressive use of these tools in isotope hydrology. The applications of environmental isotopic tracers should be enormously multiplied and promoted worldwide in the coming years for ensuring sustainable management of freshwater resources.

Glossary

Anthropogenic Relating to or resulting from the influence of human beings on nature.

Apohic zone The deep zone of an ocean or lake receiving too little light to permit photosynthesis.

Asthenosphere The ductile part of the earth just below the lithosphere, including the upper mantle.

Benthic nepheloid layer Relatively more turbid water layer near the bottom of the ocean.

Biomagnification Any concentration of chemicals in the tissues of tolerant organisms at successively higher levels in a food chain.

ϵ_{Nd} Epsilon notation where one epsilon unit represents a one part per 10,000 deviation from the Chondritic Uniform Reservoir (CHUR) isotopic composition of Nd.

Grand Ocean Conveyor Belt Thermohaline circulation that derives a global-scale system of currents.

HPGe detectors High Purity Germanium (HPGe) Radiation Detectors.

Lithosphere The outer solid part of the earth, including the crust and upper mantle.

Mass extinction Any substantial increase in the amount of extinction (lineage termination) suffered by more than one geographically wide-spread higher taxon during a relatively short interval of geologic time, resulting in at least a temporary decline in their standing diversity.

Nucleosynthesis The process of creating new atomic nuclei (chemical elements) from preexisting nucleons.

Primeval Of or resembling the earliest ages in the history of the world

Primordial Existing at or from the beginning of time.

Sv One Sverdrup (Sv) is equivalent to a volume transport of one million cubic meters per second. The volume flux unit *Sverdrup* (Sv) is widely used, after the Scandinavian pioneer meteorologist/oceanographer Harald Ulrik Sverdrup (1888–1957).

Tectonic plate A massive irregularly shaped slab of solid rock, generally composed of both continental and oceanic lithosphere. The plate size can vary greatly from a few hundred to thousands of kilometers across the globe.

Abbreviations

AMOC Atlantic meridional overturning circulation

AMS Accelerator mass spectrometry

CF Concentration factor

ITCZ Intertropical convergence zone

SPM Suspended particulate matter

THC Thermohaline circulation

TSPM Total suspended particulate matter concentration

Introduction

The ocean is vast, covering $3.6 \times 10^8 \text{ km}^2$, equivalent to approximately 72% of the earth's surface. It contains about $1.37 \times 10^{18} \text{ m}^3$ of water, and its mean depth is $3.8 \times 10^3 \text{ m}$ (Broecker and Peng, 1982). The world ocean provides the air we breathe by producing over half of the world's oxygen and absorbs 50 times more carbon dioxide than our atmosphere, regulating climate by transporting heat from the equator to the poles. The importance of seafood and other marine natural products in a balanced diet has been widely recognized by the full world human population.

"Climate refers to the average weather in terms of the mean and its variability over a certain period and a certain area. The classical period for averaging these variables is 30 years, as defined by the World Meteorological Organization." (IPCC, 2018). Thus, climate change refers to a change in the state of the climate due to natural or man-made forces, while the climate treaty of the United Nations Framework Convention on Climate Change 1992 (UNFCCC) defines climate change as "a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods" (Article 1.1). In this article, the former definition is used. The role of the oceans in climate may be best understood as a thermal lag on the climate variation due to its vast heat capacity. Oceans exchange with the atmosphere large quantities of heat, water, gases such as carbon dioxide and dimethyl sulphide, particles, and momentum. It is an important part of the global redistribution of heat from tropics to polar regions that keeps our planet habitable (e.g., Bigg et al., 2003). The grand thermohaline circulation of the global ocean, so called Grand Ocean Conveyor Belt, is the major mechanism by which the ocean contributes its share to the poleward heat transport required to counteract the Earth's surface radiation imbalance. This cyclic action repeats itself over a time period of about 1000 years. In the longer term, over a time scale of greater than 10,000 years, plate tectonics have shaped the distribution of land masses and ocean basins throughout the history of the Earth. Hence, the geologic time scales referred to eras of Precambrian, Paleozoic, Mesozoic, and Cenozoic and their individual periods, epochs and ages, are terms reflecting major climate and biological species compositional changes that have occurred in our planet.

About 4.6×10^9 years ago our solar system formed from a cloud of gas and dust that slowly contracted under the mutual gravity of all particles. The cloud was made largely of hydrogen (H) with some helium (He) and small amounts of the remaining naturally occurring chemical elements. The elements larger than He had to be produced in supernovae. Primordial radionuclides are residues from the Big Bang, from cosmogenic sources, and from ancient supernova explosions that occurred before the formation of the solar system. Bismuth (^{209}Bi , $t_{1/2} = 4.6 \times 10^{19} \text{ a}$), thorium (^{232}Th , $t_{1/2} = 14.05 \times 10^9 \text{ a}$), uranium (^{238}U , $t_{1/2} = 4.468 \times 10^9$; ^{235}U , $t_{1/2} = 704 \times 10^9$) and potassium (^{40}K , $t_{1/2} = 1.25 \times 10^9 \text{ a}$) are typical primordial radionuclides because they have half-lives long enough to still be found on the Earth. These radionuclides continue to undergo radioactive decay and produce heat in the core of the earth, turning iron into a convecting dynamo that maintains a magnetic field strong enough to shield the Earth from the solar wind and cosmic-ray particles. This molten iron leaks out into the mantle, causing convection in the rock that moves crustal plates and fuels volcanoes (Lee and Jeanloz, 2003; Sanders, 2003).

The origin of the primordial natural radionuclides of the earth is associated with the phenomenon of nucleosynthesis in stars (Garcia, 2021). The fact that the uranium, thorium, and actinium decay chains are found in the Earth is owing to the long half-lives of the parents of these chains. These primordial radionuclides have witnessed the evolution of the Earth system from its birth. Therefore, deciphering the nature of the presence of these radionuclides in various phases of the Earth is crucial to understand the past changes that occurred in the Earth over the billions of years ago. Also, the Earth since its birth is constantly bombarded by galactic cosmic rays, which primarily consist of protons and helium nuclei (Vermeesch, 2020). The primary cosmic rays managed to pass through the Earth's magnetic field, strongly interacting with the atmospheric molecules and producing secondary cosmic ray showers, mostly made of nucleons, muons and gamma-rays. Only a small fraction of the secondary cosmic rays reaches the surface of the Earth. The produced neutrons and protons then collide with the elements in the atmosphere and produce many cosmogenic radioactive and stable nuclides.

Determining the dates corresponding to climate and biota changes, as well as deciphering their underlying causes, are crucially important to investigate the underlying earth processes and also to predict the future climate changes. The natural radionuclides, along with anthropogenic radionuclides with known input functions, provide powerful means to investigate various earth processes—including the ocean. They allow the understanding of large-scale ocean circulation, input and formation of particulate matter in the ocean and its subsequent settling and decomposition in the water column, and accumulation and burial in the seafloor. These oceanic processes, with transfer of energy and material, play a crucial role in shaping the current climate of the Earth. The scientific understanding of the oceans' dynamics and their evolution over time is required to manage the wealth and sustainability of the ocean. In this regard, nuclear technology has been instrumental in tracing the movement of energy and material through the various oceans and through other compartments of the Earth, such as the atmosphere, cryosphere, and lithosphere both globally and locally. The rates and fluxes of material and energy occurring in the oceans examined by radionuclides are yielding many practical applications for sustainable management of the oceans.

Evolution of land and ocean through geologic history

The initial rotation or tumbling motion of our planetary system was accelerated as the nebula contracted, like a spinning skater who pulls in his arms to spin faster. Within the disc, the largest concentration of matter was in the center. This became the sun. Matter collected in smaller clumps out in the disc. These became the planets. The proto-sun and proto-planets grew by accretion. The materials that accreted into the early Earth were probably added piecemeal, without any particular order, by numerous collisions between small objects to form larger ones (Yu and Jacobsen, 2011). The early Earth was extremely hot from (1) gravitational compression, (2) impacts, and (3) radioactive decay. The early Earth was probably partially or largely molten. The denser metallic liquids sank to the center of the Earth and less dense silicate liquids rose to the top. In this way the Earth was very quickly differentiated into a metallic, mostly iron core and a rocky silicate mantle. Through igneous (volcanic and intrusive) activity, the crust of the Earth eventually formed.

At the same time, the atmosphere and the oceans accumulated gradually over billions of years with continual degassing of the Earth's interior. The ocean formed with the escape of water and other gases from the molten rocks of the Earth to the atmosphere surrounding the cooling planet. After the Earth's surface had cooled to a temperature below the boiling point of water, rain began to fall for centuries. As the water drained into the great hollows in the Earth's surface, the primeval ocean came into existence. This occurred as early as 4.4 billion years ago when the continent started to grow (Hadean Eon, Precambrian Era). This time period was determined by ^{40}Ar dating technology (Cawood et al., 2013; Guo and Korenaga, 2020). Argon is an inert gas that land masses emit into the atmosphere. It is a product of the radioactive decay of the primordial radionuclide, ^{40}K , that remained in the crust and mantle of continents. The ^{40}K , which decays to ^{40}Ar , was transferred to the continental crust from the mantle during partial melting, and part of it was recycled back into the mantle through subduction. About 5–6% of the Earth's mantle is made of recycled crust. The rates of crust formation were regarded similar to what they are today (Yang et al., 2020).

The forces of gravity prevented the water from leaving the planet. The Earth's solid outer crust, the lithosphere, is separated into plates that move over the asthenosphere, the molten upper portion of the mantle. Oceanic and continental plates come together, spread apart, and interact at boundaries all over the planet. Each type of plate boundary generates distinct geologic processes and landforms. At divergent boundaries, plates separate, forming a narrow rift valley. Here, geysers spurt super-heated water and magma, or molten rock, which rise from the mantle and solidify into basalt, forming a new crust. Thus, at divergent boundaries, oceanic crust is created. The mid-ocean ridge, the Earth's longest mountain range, is formed at the divergent boundary. It usually rises above about 2000 m from the sea floor but also rises above sea level (e.g., Iceland). Currently it is 5000 km long and 1500 km wide. The total length of the mid-ocean ridge has varied along the breakup of supercontinents, thus, impacting the atmospheric CO_2 concentration (Müller and Dutkiewicz, 2018).

As the seawater continues to percolate downward through fractured ocean crust along the volcanic ocean ridge system, it is first heated and then undergoes chemical modification through reaction with the host rock as it continues downward, reaching $>400^\circ\text{C}$. At these temperatures the fluids become buoyant and rise rapidly back to the seafloor where they are expelled into the overlying water column. Therefore, seafloor hydrothermal circulation plays a significant role in the cycling of energy and mass between the solid earth and the ocean to result in changes in seawater composition (e.g., von Damm, 2000) and it has changed seawater composition throughout the geological times (Antonelli et al., 2017).

At convergent boundaries, plates collide with one another. The collision buckles the edge of one or both plates, creating a mountain range or subducting one of the plates under the other, creating a deep seafloor trench. At convergent boundaries, continental crust is created, and oceanic crust is destroyed as it subducts, melts, and becomes magma. The highest mountain range above the sea level, the Himalayas, was formed 55 million years ago (Eocene Epoch of Tertiary Period, Cenozoic Era) when the Eurasian and Indo-Australian continental plates converged. Therefore, the ocean basins are to be recognized as transient features over geologic time, changing shape and depth due to the dynamic processes of plate tectonics that have occurred relentlessly.

Ocean basins

Tectonic plates have been known to form a supercontinent, then break away to drift for a while, and then aggregate again to form a supercontinent over the time scale of approximately 600 My. These recurring gatherings and dispersals of the continents have occurred throughout Earth's history (Nance et al., 2014). This assembly and breakup of continents have profoundly influenced the evolution of the geosphere, hydrosphere, atmosphere, and biosphere—including the climate changes of the Earth. Notable supercontinents having appeared so far include Ur (~ 3 Ga; Archean), Kenorland (~ 2.4 Ga; Neoproterozoic), Columbia/Nuna (~ 1.7 Ga; Paleoproterozoic), Rodinia (~ 1 Ga; Neoproterozoic), Pannotia (~ 600 Ma; Neoproterozoic ago), and Pangea (~ 250 Ma ago; Triassic). The abbreviation of Ga and Ma refer to giga years ago and million years ago, respectively.

The Pangea supercontinent has been breaking up to form the current continent and ocean. It is moving to form the next supercontinent (Amasia or Pangea Ultima, or Novopangea, or Aurica) over the next 200–300 My. The Arctic Ocean and the Caribbean Sea will disappear, and Asia will crash into the Americas by that time (Davies et al., 2018). It is clear that the distribution of continents and oceans was different from that of present day in the past and it will continue to be so in the future. For example, the huge landmasses Gondwana and Laurussia and other small ones were in the southern hemisphere in the early Devonian Period (ca. 410 My before present). In the next 200 My, most of the continental masses were gradually brought together to form a supercontinent called Pangea (Fig. 1; Domeier and Torsvik, 2014).

The fragmentation of Pangea led to the formation of an internal ocean (the present-day Atlantic Ocean) and partial consumption of the surrounding ocean (the present-day Pacific Ocean) around 180 million years ago. Currently, the spreading centers are mostly located in the oceanic ridges and their half spreading rates are fast as much as 100 mm per year (Fig. 2; Müller et al., 2008). This means that the age of the oceanic crust is young in the ridge crest, whereas the spreading ridges could be as much as 300 My old at the brink point of sinking back into the mantle in the subduction zone (e.g., Philippine Sea) (Fig. 3; Müller et al., 2008). Also, the oceanic depth is found to increase from the spreading ridge (~2500 m) to over 6000 m near the subduction zone (Hiller and Watts, 2005). It is generally thought that we are presently halfway through a supercontinent cycle.

Ocean waters

The tropical ocean, which is situated approximately between 30°N and 30°S, is generally defined as the sea surface with temperature above 20 °C. Its surface area constitutes more than a half of the global ocean. However, the thermal equator migrates to the north and south seasonally. The tropical ocean is, in fact, extended almost to the area between 40°N and 40°S, and comprises more than

70% of the global ocean (Peng, 1985; IAEA, 1988), as shown in Fig. 4. Warm tropical waters accumulate heat and energy harnessed from solar radiation and move westward by trade winds. They peel off in northerly and southerly directions (e.g., western boundary currents such as the Gulf Stream and the Kuroshio in the Northern Hemisphere, East Australia Current, Agulhas Current, Brazil Current in the southern hemisphere) in places where the landmass blocks its westward movement—resulting in water being pumped in bursts that progressively move toward the poles.

The intertropical convergence zone (ITCZ) is the region that circles the Earth near the equator, where the trade winds of the Northern and Southern Hemispheres come together. The intense solar radiation and warm water of the equator heat the air in the ITCZ, raising its humidity and making it buoyant. Aided by the convergence of the trade winds, the buoyant air rises. As the air rises, it expands and cools—releasing the accumulated moisture in an almost perpetual series of thunderstorms. Therefore, it is also called the global rain belt. It migrates latitudinally on a seasonal basis. Although it remains near the equator, the ITCZ moves farther north or south over land than over the oceans because it is drawn toward areas of the warmest surface temperatures. The location of the ITCZ can vary as much as 40°N in summer on land. The typhoons and hurricanes originating in the tropics carry a large amount of heat and rain to the poleward directions. The trade winds weaken every 2–7 years, and typically last for 9–12 months, changing the climate (e.g., heavy rainfall and droughts in countries around the Pacific from Peru to Indonesia and Australia). This phenomenon (called El Niño) is also extended to the Indian Ocean (DiNezio et al., 2020).

Because of its vast influence, tropical ocean water is of primary interest. Ocean water in the tropical region may be characterized as a warm surface water and cold deep water as shown in Fig. 5 (e.g., Northwestern Pacific Ocean, GEOSECS 214; 32°1'N 176°59'W). The whole water column, therefore, can be characterized as vertically segregated by density differences, that is, heavy cold water lies beneath the light warm water in the surface (Fig. 5; Broecker et al., 1982; Ostlund et al., 1987). The two layered ocean model has been useful to understand the vertical distribution of seawater properties as well as their horizontal segregation in the global ocean (Broecker and Peng, 1982).

In Fig. 5, the salinity profile at a depth just over 600 m reflects the presence of the oxygen depleted intermediate water that forms in the northern Pacific and sinks and flows laterally beneath the waters of the warm temperate ocean. Dissolved oxygen is utilized by animals and bacterial living in the deep sea to “burn” the organic matter falling from the surface. Thus, all the deep waters are deficient in oxygen, compared to the amount they equilibrated with the overlying atmosphere. The increase of the dissolved oxygen in the deep water reflects the intrusion of northward bottom water recharged with air in the Southern Ocean. As oxygen is consumed, silicate, phosphate and nitrate are regenerated. The life processes are one of the most salient features of the oceans. The silicon, nitrogen, and phosphorus are the essential constituents of the marine lives, along with carbon.

Three major types of particles formed in the sunlit surface ocean through photosynthesis are organic matter (e.g., Redfield molecule, $C_{106}H_{263}N_{16}P$), calcium carbonate ($CaCO_3$), and opaline silica (SiO_2). The plant and animals produce calcium carbonate tests or opaline silica frustules in the sunlit surface ocean and those particulate matters are decomposed or dissolved while they sink through the water column. A fraction of them arrive at the sea floor and are eventually buried there.

The ocean regulates the climate of the Earth (our human habitat) by the redistribution of heat from the tropics to the poles through its deep-water circulation (conveyor belt) and the exchange of the most important climate gas (carbon dioxide) through thermohaline ocean circulation and biological pumping. The biological pump refers to a particulate form of carbon transported

Fig. 4 Global sea surface temperature. Temperatures in squares are in degree Celsius (°C). Courtesy of Lamont Doherty Geological Observatory, 2020.

from the sunlit surface ocean to the dark deep sea and sea floor. In the real-world ocean, the concentrations of the biologically active constituents (e.g., dissolved SiO_2 (noted as $\text{Si}(\text{OH})_4$), NO_3^- , PO_4^{3-}) show considerable geographic and depth variability. As shown in Fig. 5, the concentrations of the biologically active constituents increase with depth in the North Pacific to a mid-depth maximum and then decrease somewhat toward the bottom. This type of profile characterizes the Pacific and Indian Oceans from the equator to about 40°N and 40°S. In the Atlantic, the concentrations of these constituents increase all the way to the bottom. In the deep water below 1000 m depth, the nutrient concentrations increase from the Atlantic sequentially to the Indian, South Pacific, and North Pacific oceans due to the thermohaline deep-water circulation, so called Great Ocean Conveyor Belt (Fig. 6; NOAA, 2020).

Marine biological organisms

It is important to recognize that oceanic water bodies contain many forms of life, largely supported by the organic matter produced by phytoplankton through photosynthesis converting carbon dioxide and nutrients in seawater using solar radiation in the upper euphotic 200 m water column. Chemosynthesis also occurs in some localized locations using reduced sulfur in oceanic ridges (e.g., 1 km long and several hundred meters wide, the Pacmanus hydrothermal vent field in the eastern Manus Basin, Papua New Guinea; Van Dover et al., 2018) or using hydrocarbons (usually methane) seeped from the organic matter rich continental margins (e.g., 1000 m² in the Peruvian margin; Tunnicliffe et al., 2003).

The intensity of light rapidly dissipates as depth increases, especially beyond a depth of 100 or 200 m. The zone between about 100–200 m and 1000 m is usually referred to as the “twilight” zone, which is usually substantially colder than the surface. About

Fig. 5 Depth profiles of potential water temperature ($^{\circ}\text{C}$) corrected for the adiabatic pressure, salinity (‰ , by weight), potential density (σ_{θ} , the density calculated using in situ salinity and potential temperature minus 1000 kg m^{-3}), dissolved oxygen ($\mu\text{mol/kg}$), dissolved silicic acid (SiO_2 , $\mu\text{mol/kg}$), phosphate ion ($\mu\text{mol/kg}$), nitrate ion ($\mu\text{mol/kg}$) at GEOSECS station 214 in the North Pacific ($32^{\circ}1'N$ $176^{\circ}59'W$). Fig. 6 The path of the global ocean conveyor belt. The blue arrows indicate the path of deep, cold, dense water currents. The red arrows indicate the path of warmer, less dense surface waters. It is estimated that it can take 1000 years for a parcel of water to complete the journey along the global conveyor belt. From NOAA (2020) The Global Conveyor Belt. National Oceanic and Atmospheric Administration. https://oceanservice.noaa.gov/education/tutorial_currents/05conveyor2.html.

90% of particulate organic matter sinking from the upper water column is decomposed in this twilight zone (Buesseler et al., 2020), thus playing a major role in removing carbon dioxide from the atmosphere and storing it for centuries or longer in the ocean. It is also privy to the largest migration on Earth. Huge numbers of fishes and zooplankton move hundreds of meters toward the surface to feed, before retreating down at dawn.

The twilight zone has been increasingly recognized for its importance in maintaining a healthy ocean. Phytoplankton growing in the sunlit layer fuel multiple food supply routes into the zone that sustain organisms from bacteria to giant squid. In the process of consuming this food, and each other, the twilight zone animals produce CO_2 , consume oxygen, and release nutrients back into the water as shown in the depth distributions of phosphate and nitrate in the North Pacific (Fig. 5). In the winter, cold and windy weather mixes the deep-water rich in the regenerated nutrients with water from the surface layer. In this way, the twilight zone has an important role in supporting phytoplankton growth in next spring. Although winter mixing can release carbon back into the atmosphere, a large fraction of carbon ends up in deeper waters where it can be locked away, typically for centuries. This downward transport of organic matter, mediated by life in the twilight zone, is called the biological carbon pump, and the twilight zone is central to its strength. This deeper flux of materials becomes food for the animals there. The small amount that eventually reaches the sea floor sustains everything from bacterial to sea cucumbers.

The aphotic, or “midnight,” zone exists in depths below 1000 m of the abyssal ocean. Sunlight does not penetrate the ocean deeper than 1000 m, beyond which it is shrouded in utter darkness. Biological organisms metabolize continuously in the abyssal ocean deeper than 4000 m, but their metabolic rates have been observed to be significantly lower than those in shallow water due to the increased hydrostatic pressure and/or diminished food and chemical energy available—rather than cold water temperature (Brown et al., 2018).

Behavior of radionuclides in the sea

The oceans and coastal waters are influenced by a complex variety of physical, geochemical and biological processes, which influence the behavior, transport and fate of radionuclides released into the marine environment. Among them, suspended particulate matter and biological organisms are of interest in terms of the transport and fate of radionuclides in the sea (Fig. 7; Benitez-Nelson et al., 2018). Although the suspended particulate matter is present at an order of a few tens of parts per billion ($\mu\text{g}/\text{kg}$) level, it scavenges metallic elements such as Th, Pu, Fe, Pb, and Cu from the ocean water column, thereby controlling their concentrations. The

Fig. 7 Schematic diagram of the U-Th series radionuclides utilized to understand various processes occurring in the ocean using different chemical affinity to water borne particles between daughter and parent radionuclides. From Benitez-Nelson CR, Buesseler K, Dai M, Aoyama M, Casacuberta N, Charmasson S, Johnson A, Godody JM, Maderich V, Masqué P, Moore W, Morris PJ and Smith JN (2018) Radioactivity in the marine environment: Understanding the basics of radioactivity. *Limnology and Oceanography e-Lectures*. doi: 10.1002/loe2.10010. with permission.

suspended particulate matter is mostly made out of biogenic matter produced by phytoplankton in the upper water column, and it undergoes decomposition and dissolution during their decent. Therefore, a part of radionuclides once scavenged by suspended particulate matter is subject to be released in the deeper depth. This intricate nature of chemical processes is occurring relentlessly throughout the ocean water column and the benthic nepheloid layer adjacent to the sea floor (e.g., Lal, 1977).

Metallic radionuclides and suspended particulate matter

Many of the radionuclides introduced into the marine environment are likely to be taken up by organisms or adsorbed onto suspended and settling particulate matter in the water column and bottom sediments, e.g., Pu, Am. However, some metallic elements such as U, Pb, Cs, and Pu are largely present in the form of dissolved species in the ocean interior due to the low amount of suspended particulate matter (on the order of a few tens of $\mu\text{g/kg}$ or less). For example, the isotopes ^{239}Pu and ^{240}Pu are still largely present in the dissolved phase after their introduction more than seven decades ago (Hong and Povinec, 2021). Once introduced into the sea, they are ionized and dissolved in seawater and adsorbed onto the surface of particulate matter. Some of them are actively taken up by the plants and animals. In general, metal species present in seawater are in a form of free metal ions, inorganic pairs ($< 1\text{ nm}$), inorganic complexes, organic complexes, chelates, metal species bound to high molecular weight organic material ($< 10\text{ nm}$), metal species adsorbed on colloids ($< 10\text{ nm} \sim < 120\text{ nm}$) or aggregated colloids ($\sim < 0.2\text{ }\mu\text{m}$), and adsorbed on particulate matter ($\sim > 0.2\text{ }\mu\text{m}$) (Stumm and Morgan, 1981).

The combined amount of free metal ions, inorganic pairs, inorganic complexes, organic complexes, chelates, and metal species bound to high molecular organic material ($< 10\text{ nm}$) may be considered as the truly dissolved phase. For example, about 35%, 49%, 16% of ^{210}Pb are found in dissolved, colloidal, and particulate phases, respectively, while 21%, 34%, and 44% of ^{210}Po in the upper 200 m water column of a marginal sea of the Northwest Pacific are found in dissolved, colloidal, and particulate phases (Kim and Kim, 2012). However, it is often difficult to separate dissolved and colloidal substances at sea. The dissolved phase is operationally defined as the sum of truly dissolved and colloidal phases, and the cutoff diameter is usually taken as about $0.4\text{ }\mu\text{m}$. The metal fraction below the cutoff diameter is defined as the dissolved phase, where the metal fraction above the cutoff diameter is defined as the particulate phase. In order to understand the portion of particulate phase of metallic radionuclides, the distribution coefficient (K_d) is operationally defined as the ratio of the metallic contents between particulate and dissolved phases (Eq. 1).

$$K_d = \frac{C_p}{C_d \times \text{TSPM}} \quad (1)$$

where C_p (Bq/L of water) and C_d (Bq/kg) are activity concentrations of radionuclides in particulate and dissolved phases of seawater, respectively, and TSPM ($\mu\text{g/L}$ of water) is the total suspended particulate matter concentration. K_d values (L/kg) for metals or radionuclides are largely determined from seawater concentration and suspended particulate matter in a given parcel of water. For the modeling studies, IAEA (2004) have compiled K_d values with respect to pelagic clay and shale. Their values may be regarded as an upper limit, as most particulate matter in the ocean proper away from the coast is composed of many biologically produced particles of calcium carbonate, siliceous frustules, and organic matter that may be less adsorbed by metallic elements. Selected K_d values are listed in Table 1 (IAEA, 2004).

If TSPM is known, the relative proportion of metal concentrations in the particulate and dissolved phases may be estimated by the modification of Eq. (1).

$$\frac{C_p}{C_d} = K_d \cdot \text{TSPM} \quad (2)$$

The total concentration of a radionuclide (C_t) is the sum of $C_p + C_d$. Therefore, a fraction of particulate phase over total amount of metal or radionuclide (Eq. 2) may be estimated using Eq. (3).

$$\frac{C_p}{C_t} = \frac{C_p}{C_p + C_d} = \frac{1}{1 + \frac{1}{K_d \cdot \text{TSPM}}} \quad (3)$$

Table 1 Distribution coefficient of selected elements (recommended values taken from IAEA, 2004).

Element	K_d (L/kg)	Phytoplankton	Zooplankton	Crustacean muscle	Fish fillet (surface water)	Cetaceans muscle (whale, dolphins, porpoises)
Sr	2×10^2	1×10^0	2×10^0	5×10^0	3×10^0	
Tc	1×10^2	1×10^3	1×10^3	1×10^3	1×10^1	
I	2×10^2	8×10^2	3×10^3	3×10^0	9×10^0	
Cs	2×10^3	2×10^1	4×10^1	5×10^1	1×10^2	3×10^2
Pb	1×10^7	1×10^5	1×10^3	9×10^4	2×10^2	4×10^4
Po	2×10^7	7×10^4	3×10^4	2×10^4	2×10^3	
Th	5×10^6	4×10^5	4×10^3	1×10^3	6×10^2	
Pu	1×10^5	2×10^5	4×10^3	2×10^2	1×10^2	
Am	2×10^6	2×10^5		4×10^2	1×10^2	
U	5×10^2	2×10^1				

Since the K_d value of stable Pb in the ocean is about 1×10^7 and the concentration of dissolved Pb is 4.0×10^{-15} Pb g/L (IAEA, 2004), the C_p/C_d ratio should be equal at the TSPM of 100 $\mu\text{g/L}$. However, in the open ocean, it is still rare to witness simultaneous measurements of suspended particulate matter concentration and particulate radionuclide activity concentration. For example, without determining TSPM concentrations directly, particulate ^{210}Pb values are reported to account for less than 10% in most subsurface waters, and close to 40% in near bottom turbid waters in the global ocean. This is determined by measuring the ^{210}Pb activity concentration in the solid retained on the filter and in the filtrate (Rigaud et al., 2015; Nidermiller and Baskaran, 2019). Therefore, recommended values given by IAEA (2004) should be regarded as maximum estimates. It is also noted that the distribution coefficient as a quotient of activity concentration in ^{210}Pb in particulate and dissolved phases is inversely proportional to the concentration of TSM. In turbid coastal waters where TSPM concentration is greater than mg/L level (e.g., the Yellow Sea, Hong et al., 1999), a few tens of $\mu\text{g/L}$ level of TSPM are found in the deep ocean. The fraction of particulate phase of ^{210}Pb and ^{210}Po were found to reach almost 100% in seawater with concentrations greater than 4 mg/L (Hong et al., 1999).

Concentration factors

For a given substance in a liquid, the ratio of its concentration in the two different phases is constant at a given temperature, provided that the molecular state of the distributed solute is same in both phases according to Nernst's distribution or partition law. It is expressed as $CF = C_1/C_2$ where C_1 and C_2 are the concentrations of the solute in phase 1 and phase 2, respectively. C_2 is usually the concentration of a given substance in a liquid phase, operationally defined as the phase of less than 0.4 μm in this study. CF is called concentration factor in the case where C_1 is the concentration in biological organism phase (Eq. 4), assuming they are in equilibrium and the uptake rate is much shorter than the observation frequency.

$$CF (\text{L/kg}) = \frac{\text{Concentration per unit mass of organism} \left(\frac{\text{Bq}}{\text{kg wet weight}} \right)}{\text{Concentration per unit volume of seawater} \left(\frac{\text{Bq}}{\text{L}} \right)} \quad (4)$$

A strong positive correlation was observed for many metallic radionuclides, such as ^{137}Cs levels in the muscle of phytoplankton, zooplankton, crustacean, fish, cetaceans (Table 1). Bioavailability of a given substance may be strongly dependent upon the specification of the substance where the free ion form is commonly believed to be the bioavailable form for direct uptake from seawater. It should be noted that, except for algae, the term CF as used here does not imply that all the elements within the organism are concentrated by direct accumulation from the water. It is simply a value that relates the concentration in the organism, which may have been derived by uptake from sea water, particulate matter, and food, to that of the medium in which it lives (IAEA, 2004).

Biomagnification

Biomagnification, also known as bioamplification or biological magnification, is any concentration of a toxin, such as pesticides or metals, in the tissues of tolerant organisms at successively higher levels in a food chain. Concentration factors for selected radionuclide metals are compared among various trophic level organisms to elucidate whether they are biomagnified through the higher food web (Fig. 8; IAEA, 2004). Among the elements Cs, Pb, Po, Pu, Am, Cesium (Cs) appears to be biomagnified in a higher food web in the phytoplankton-zooplankton-fish food chain, and Pu in a higher food web in the macroalgae-molluscs, e.g., abalone (Kim et al., 2020). The ^{137}Cs bioaccumulation is driven by relatively rapid dietary uptake rates, moderate depuration rates in lower trophic level organisms and slow elimination rates in high trophic level organisms.

Uptake kinetics of radionuclides from water

The massive ^{137}Cs released into the sea from the Fukushima Dai-ichi Nuclear Power Plant (FDNPP) accident in 2011, and subsequent large-scale time-series measurements in both seawater and fish, provided a rare opportunity to observe the relationship between CF and the exposure time. The ^{137}Cs concentrations in seawater ranged from < 10 Bq/kg in 2016 (Hori et al., 2018) to about 1000 Bq/kg ($^{134}\text{Cs} + ^{137}\text{Cs}$) at the beginning of the accident in 2011 (Povinec et al., 2013a). Wang et al. (2018) collated those data during the initial 400 days and they found the time series variation of ^{137}Cs activity in fish flesh depended on the activity concentration in seawater and as a function of time. For the pelagic fish and for the surface seawater, ^{137}Cs (Bq/kg) = $305.51e^{(-0.012 \times \text{day})}$ ($R^2 = 0.448$) ($n = 102$) and ^{137}Cs (Bq/L) = $53.442e^{(-0.023 \times \text{day})}$ ($R^2 = 0.921$, $n = 2042$) were observed, respectively. R^2 and n refer to the square of sample correlation coefficient, and size of samples, respectively. If we calculate CF using the two equations, CF of ^{137}Cs in pelagic fish flesh is given as a function of time, $CF = 5.71e^{(0.011 \times \text{day})}$. This equation suggests that the exposure time is a limiting step for the accumulation of ^{137}Cs in the sea. The obtained CF value of 316 at the 365th day may be a little higher than the average values reported.

A similar feature was observed in a higher-trophic level animal than fish, such as marine mammals. The salmon-resident killer whale food web ^{137}Cs bioaccumulation model outcomes show that ^{137}Cs can be expected to gradually bioaccumulate in the food web over time as demonstrated by the increase of the apparent trophic magnification factor of ^{137}Cs , ranging from 0.76 after 1 month of exposure to 2.0 following 30 years of exposure (Alava and Gobas, 2016). In general, a substance including radionuclide

Fig. 8 Concentration factors of Cs, Pb, Po, Pu and Am. Data from IAEA (2004) Sediment distribution coefficients and concentration factors for biota in the marine environment, 103 p. Vienna: International Atomic Energy Agency, Technical Report Series no. 422.

accumulation in biological organisms in water has been described by the following first-order reaction in Eq. 5 with respect to the concentration of the substance in water and prey material (cited in Wang et al., 2000).

$$dC/dt = k_u \cdot C_w + AE \cdot IR \cdot C_f - k_e \cdot C \quad (5)$$

where C is the radionuclide concentration in the animal organs at time t ($\mu\text{g/g}$ dry or wet wt. or Bq/g), k_u is the radionuclide uptake rate constant from dissolved phase (L/g day or L/Bq day), C_w is the radionuclide concentration in seawater ($\mu\text{g/L}$ or Bq/L), AE is the radionuclide assimilation efficiency, IR is the animal's food particle ingestion rate ($\text{g/g of body wt}^{-1} \text{ day}^{-1}$), C_f is the radionuclide concentration in the ingested food particles ($\mu\text{g/g}$ or Bq/g), and k_e is the radionuclide efflux rate constant (day^{-1}). All weight units of tissues were in dry or wet weight. Eq. (6) assumes that the body concentration change with time is a function of the radionuclide concentration of seawater and concentration of prey organisms. This tacitly assumes the uptake via seawater and uptake by consumption of prey are both instantaneous reactions. The rate constant for uptake from the dissolved source (k_u) is metal and species specific and is an indicator of bioavailability of dissolved metals (Lee et al., 1998). The radionuclide concentration in tissues of animal at steady-state, C_{ss} , can be calculated as:

$$C_{ss} = (k_u \cdot C_w + AE \cdot IR \cdot C_f) / k_e \quad (6)$$

If animals are not fed, radionuclide uptake occurs only from seawater, and the ratio of rates of uptake over depuration (excretion) in Eq. (5) at steady state is the ratio of concentration in animal over concentration in water, $k_u/k_e = C_{ss}/C_w$, that is the concentration factor (CF) as defined in Eq. (4). In dilute solutions, as in the case of concentration in the order of $\text{fmol } ^{137}\text{Cs/L}$ (equivalent to 10 Bq/L of ^{137}Cs) in this study, n becomes 1, as described in the Freundlich isotherm ($C = \text{CF} \cdot C_w^{1/n}$) shown in Lee et al. (1998)'s metal uptake experiments on the bivalves. However, the empirical Freundlich isotherm does not predict C_{ss} or an adsorption maximum that we have often observed. The Langmuir isotherm has been used widely to describe empirically the amount of adsorbate per unit mass of adsorbent as a function of the adsorbate concentration remaining in solution to predict the adsorption maximum at equilibrium (Eq. 6). Smith (1999) briefly summarized the Langmuir isotherm as following Eq. (7)

$$q = \frac{kbC}{1 + kC} \quad (7)$$

where q is the amount of adsorbate per unit mass of adsorbent, C is the adsorbate concentration remaining in solution at equilibrium, b is the maximum adsorption capacity of the adsorbent (monolayer coverage), and k is a constant related to the binding strength. The Langmuir isotherm assumes (i) a finite number of surface sites, (ii) no electrostatic or chemical interactions, (iii) constant binding energy for all surface sites, (iv) assuming that the binding energy is independent of the adsorption density, (v) assuming that the maximum amount of adsorption is limited to a monolayer coverage of the surface sites, and (vi) there is a large excess of substrate over adsorbent.

When the above equation is rearranged, a plot of C/q against C results in a linear representation of adsorption data with a slope of $1/b$ and an intercept of $1/kb$. In many cases, the sorption in natural systems deviates from this linear representation. Rearranging variables in Eq. (7) gives the Michaelis-Menten equation of enzyme kinetics that is also widely used to describe kinetics of nutrient uptake by phytoplankton at sea, $V_M = \frac{V_{max,s} \cdot S}{K_s + S}$, where V_M is the uptake rate for a nutrient with the concentration S , $V_{max,s}$ is the maximum uptake rate for the nutrient, and K_s is the half-saturation constant. Alava and Gobas (2016) showed that ^{137}Cs activity (Bq/kg wet wt.) in fish body followed the hyperbolic function of seawater concentration (Bq/L).

The uptake of radionuclides from the dilute solution by animals may be similar to nutrient (or metal) uptake by phytoplankton from the dilute solution of seawater. That is, nutrient (or metal) concentration in sea water is rather given at the fixed concentration, but the incorporation of nutrient (metal) into the phytoplankton cells depends on the uptake (adsorption and absorption) characteristics of the phytoplankton of concern. In this case, uptake reaction is assumed to be completed instantaneous. However, the accumulation of extracellular compartments, characterized by an initial rapid accumulation, then follows a gradual slowing down over time. The result fits perfectly to a Michaelis-Menten model (Fernandez et al., 2006). Fowler et al. (2010) also observed a hyperbolic function like uptake of ^{207}Bi as volume concentration factor (VCF) with time in phytoplankton cells. The accumulation of radionuclide in the flesh of oysters and the digestive tract of flounders may be quite similar to the other metal uptake in seawater where the metal concentration in sea water is fixed.

The purposes of this study are to look at the response of oyster and flounder with time to uptake radionuclides in seawater of a fixed concentration of the radionuclides in relatively overwhelmingly large pool of radionuclide contaminated seawater—the entire north-west Pacific Ocean. Among the radionuclides tested, ^{137}Cs accumulation in the flesh of oysters and the digestive tract of flounders with exposure time appeared to follow the hyperbolic function (Fig. 9) identical to the Michaelis-Menten equation Eq. (8).

$$\frac{\text{Bq}}{\text{kg wet wt}} = \frac{m \cdot [t]}{k + [t]} \text{ or CF} = \frac{m \cdot [t]}{k + [t]} \quad (8)$$

where t is the duration of exposure.

The accumulation rate (expressed as CF) of a given radionuclide is proportional to the exposure time with two fixed values of m and k . The m and k are maximum or steady state concentrations, and the time t is taken to reach the half the value of m . For the CF, m is the maximum or steady state CF and k is the time taken to reach half of the value of maximum CF (Fernandez et al., 2006). They further defined steady state concentration in animal tissue as the tissue concentration from which the daily increase in concentrations is less than 1% of that of the previous day. The accumulation of radionuclide in the flesh of oyster faithfully appears to follow the hyperbolic function in the unfed oyster culture experiment, $[^{137}\text{Cs} \text{ Bq/kg wet wt.}] = 54.20 \times (\text{hour})/[24.87 + (\text{hour})]$, $R^2 = 0.89$ as shown in Fig. 9. The hyperbolic function predicts that ^{137}Cs activity will reach 51.6 Bq/kg wet wt. on the 21st day, 52.9 Bq/kg wet wt. on the 42nd day, and 54.1 Bq/kg wet wt. on the 420th day of exposure (Fig. 9).

Where the ocean is turbid (more SPM), the dissolved concentration is relatively less in the dissolved in seawater. The metals concentration in fish muscle is relatively higher in clear waters than in turbid waters because dissolved phase metal is only available for bioaccumulation. For example, ^{210}Po concentration is higher in squid living in the turbid Yellow Sea ($\sim 10 \text{ mg/L} < \text{TSPM} < \sim 110 \text{ mg/L}$) compared ones living in the clear East Sea/Sea of Japan where the TSPM is generally $< 0.55 \text{ mg/L}$ (Waska et al., 2013; Chen et al., 1996).

Climate change and the ocean

The level of atmospheric CO_2 concentration is measured as a dry air mole fraction, defined as the number of molecules of carbon dioxide divided by the number of molecules in air including CO_2 itself, after water vapor has been removed. The mole fraction is

Fig. 9 ^{137}Cs accumulation in oyster flesh appears to follow the hyperbolic function, $y = m \cdot x/(k + x)$, $[^{137}\text{Cs} \text{ Bq/kg wet wt.}] = 54.20 \times (\text{hour})/[24.87 + (\text{hour})]$, $R^2 = 0.89$. The oysters were placed in each aquarium and kept unfed and aerated until being sacrificed. Data from Kim SH and Hong GH, unpublished.

Fig. 10 Monthly mean carbon dioxide measured at Mauna Loa Observatory, Hawaii. The observatory is located on the north flank of Mauna Loa Volcano, on the Big Island of Hawaii, at an elevation of 3397 m and it has started in 1959 (316 ppm, annual average). The annual mean rate of growth of CO_2 has steadily increased from 0.94 ppm in 1959 to 2.46 ppm in 2019. Courtesy of NOAA, https://www.esrl.noaa.gov/gmd/webdata/ccgg/trends/co2_data_mlo.png.

expressed as parts per million (ppm). The current level of CO_2 in the air (June 2020) is about 416 ppm (Fig. 10; NOAA), much higher than that of preindustrial levels (~ 280 ppm) in 1750.

For the last decade (2009–18), combustion of fossil fuels including other industries (e.g., cement production) emits 9.5 ± 0.5 Gt C (giga ton carbon) annually into the atmosphere. A land use change emits 1.5 ± 0.7 Gt C annually to the atmosphere. The land use change here refers to clearing forest or grassland that emits the stored carbon dioxide, methane, and nitrous oxide in soil to the atmosphere. The emitted carbon dioxide accumulated in the atmosphere, ocean, and land is as much as 4.90 ± 0.02 Gt C, 2.5 ± 0.6 Gt C, and 3.2 ± 0.6 Gt C, respectively, with a budget imbalance of $0.4 \text{ Gt C year}^{-1}$ indicating over estimated emissions and/or underestimated sinks (Friedlingstein et al., 2019). About 829 Gt C of carbon is currently stored in the atmosphere, and 40,453 Gt C in the ocean (Fig. 11; IPCC, 2013).

Most carbon dioxide released into the atmosphere will eventually be absorbed by the ocean. Thus, it results in the acidification of surface ocean to decrease the pH of the oceanic surface waters from the preindustrial level of 8.2 to down to 7.8 (H^+ concentration rises by 150% (e.g., Gattuso et al., 2015, Caldeira and Wickett, 2003). At the same time the warmed atmosphere heats the surface ocean resulting in enhancing stratification, thereby decreasing nutrient availability to phytoplankton growth. Therefore, the global warming due to the increase in greenhouse gas concentrations, especially carbon dioxide, induces a significant change in the ocean chemistry (e.g., pH) and primary productivity (Gao et al., 2019).

We can see that the ocean is extremely important in the study of atmospheric carbon dioxide since it is such a large reservoir in intimate contact with the air. As soon as CO_2 migrates from the atmosphere into the water, where its concentration is lower than that of the overlying atmosphere, it reacts chemically with water molecules to form carbonic acid, which causes a shift in the concentrations of the hydrogen carbonate (HCO_3^-) and carbonate (CO_3^{2-}) ions that are derived from the carbonic acid. Because carbon dioxide is immediately processed in the sea, the CO_2 storing capacity of the oceans is 10 times higher than that of freshwater. Hence, the ocean can absorb large quantities of CO_2 . When a new carbon equilibrium between the atmosphere and the world ocean is re-established in the future, the oceanic reservoir will have assimilated around 80% of the anthropogenic CO_2 from the atmosphere, primarily due to the reaction with carbonate. The buffering effect of deep-sea calcium carbonate sediments is also important. These carbonates neutralize large amounts of CO_2 by reacting and dissolving it to some extent. Thanks to these processes, the oceans could ultimately absorb around 95% of the anthropogenic emissions. Because of the slow mixing of the ocean, however, it would take centuries before equilibrium is established. The very gradual buffering of CO_2 by the reaction with carbonate sediments might even take millennia.

For today's situation, this means that a marked carbon disequilibrium between the ocean and atmosphere will continue to exist for the decades and centuries to come. Therefore, the world ocean cannot absorb the greenhouse gas as rapidly as it is emitted into the atmosphere by humans. The absorptive capacity of the oceans through chemical processes in the water is directly dependent on

Fig. 11 Schematic of the global carbon cycle. From IPCC (2013) *Climate Change 2013: The Physical Science Basis*. Contribution of Working Group I to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change. [Stocker TF, Qin D, Plattner G-K, Tignor M, Allen SK, Boschung J, Nauels A, Xia Y, Bex V, and Midgley PM (Eds.)]. Cambridge, United Kingdom and New York, NY, USA: Cambridge University Press, 1535 pp.

the rate of water mixing in the world ocean. Thus, the current oceanic uptake of CO_2 lags significantly behind its chemical capacity as the present-day CO_2 emissions occur much faster than they can be processed by the ocean (Bollmann et al., 2010).

If humans double atmospheric carbon dioxide from the pre-industrial levels (280 ppm to 560 ppm) within the next 40 years, and if the build-up of CO_2 continues at current rates (about 0.5% per year), based on the long-term record of measurements from the Mauna Loa Observatory (Fig. 10; Tans and Keeling, 2020), the likely warming range is estimated to be between 2.6°C and 3.9°C (Sherwood et al., 2020) and this will constitute a new basis for projections of sea-level rise, economic damage, and other impacts (Voosen, 2020). Heatwaves are becoming more frequent both in the land and the ocean. It is not unusual to observe dense surface blooms of toxic cyanobacteria in eutrophic lakes, leading mass mortalities of fish in lakes and rivers, and resulting in a serious health threat for cattle, pets, and humans in all over the world (Jöhnk et al., 2007). Similarly, an extensive fish kill event was found to be caused by the combination of a marine heatwave and a harmful algal bloom in South Australia (Roberts et al., 2019). A massive quantity of warm water, the Blob, suddenly appeared in the ocean area extending from Baja California in Mexico all the way to Alaska and the Bering Sea. During 2014 and 2019, it resulted in the death of many sea lions and salmon, including the production of toxic algae blooms that can poison mussels, crabs and other sea life (Amaya et al., 2020). The frequency and severity of the summertime marine heatwaves is expected to increase in various places in the ocean as the global climate warms. The impact of heat waves has been felt in almost all aspects of human activities, such as heat induced mortality increase, urban air quality deterioration, abrupt electricity demand, closing airports when the air temperature rises above 48°C , and the economic recession (Mazdiyasi et al., 2019).

Climate change is one of the important issues in our time. However, a statement like “climate change is occurring now” should be understood as “climate change is occurring now as it used to be, but at an accelerated rate.” Although human induced alternation

of the climate is certainly perturbing the natural climate system significantly, the Earth itself has undergone multiple changes over time since its formation. It will continue to do so for the next 5.4 By, until the sun will enter the red giant phase exhausting all hydrogen in the core, and the inert helium ash that will build up there becomes unstable and collapses under its own weight (Williams, 2016). In the context of the current attention to the climate change caused by human activities emitting carbon dioxide and other greenhouse gases to the atmosphere, it would be useful to look back on the climate changes that occurred in the geological past—including mass extinction of lives over time—while acknowledging the human caused changes that need to be corrected.

The effect of climate change on marine biota

Life as single-celled microbes probably began in the ocean at least 3.5 By ago (Paleo Archean Era of Archean Eon, Precambrian Era; Schopf et al., 2018). Oxygen continued to build up in the atmosphere and ocean to support complex life as photosynthesis began more than 2.5 By ago. More complex multicellular organisms evolved about 1.2 By ago (Meso-Proterozoic Era of Proterozoic Eon, Precambrian Era; Paleo Proterozoic Era of Proterozoic Eon, Precambrian Era) leading to the Great Oxidation Event. Since then, life forms have grown much diverse—though not continuously. Early life forms began to flourish during the Cambrian period (540 My). The record reveals bursts of evolution and expansion interrupted by massive extinctions that accompanied the big climate changes resulting from diverse causes. Mass extinctions—when at least half of all species died out in a relatively short time—have occurred several times over the course of our planet's history. The earliest one was Ordovician-Silurian extinction (440 My), which lasted for at least 1 My when a large portion of marine benthic animals died out due to glaciation (Wang et al., 2019). This was followed by the Devonian extinction that wiped out many tropical marine species, including reef building sponges and corals—all subject to extinction in the Devonian Period (365 My) (De Vleeschouwer et al., 2017), followed by the largest extinction event (elimination of over 95% of marine and 70% of terrestrial species in Permian-Triassic period (250 My) in the geological history of the Earth (Shen et al., 2019). More recently, the Cretaceous-tertiary extinction (K-T extinction) occurred in 66 My, when dinosaurs and the mosasaurs, plesiosaurs of land and ichthyosaurs, ammonites, and reef building bivalve rudists of the oceans disappeared. Recently, ancient specimens of rudist laying down daily growth rings revealed that Earth turned faster at the end of the dinosaurs era than it does today, rotating 372 times a year, compared to the current 365 in the late Cretaceous. (de Winter et al., 2020).
